Few more cogent examples of the justification for the painstaking and deliberate methods of scientific research have developed than is shown in the story of cevitamic acid (vitamin C). Once the evidence had been obtained that a deficiency in this food factor could be produced at will in experimental animals, great effort was made to find sources of it in nature. Concentrates were made from the richest of these and, when they had been sufficiently purified, the chemical constitution was at length established. The goal of this study was reached in 1933, when the synthesis of cevitamic acid was achieved. Thus, in the interval of a quarter of a century from the recognition of experimental scurvy, the factor the absence of which is responsible for the development of this disease was artificially prepared in the laboratory. Perhaps the story is the more thrilling because of the long history of the tacit recognition of human scurvy as a deficiency disorder. However, current events are demonstrating the value of a chemically pure food essential in medicine and the possibility of using such a substance in explaining certain biochemical phenomena.

Cevitamic acid is readily obtainable as pure white crystals, soluble in water and with a somewhat acid taste. Its value as a preventive and cure of human and experimental scurvy has been demonstrated repeatedly. Studies on scorbutic guinea-pigs have shown that the typical defects in bones and teeth caused by the disease are repaired by cevitamic acid just as they are when orange juice is administered.¹ One of the earliest signs of experimental scurvy is an increased clotting time of the blood, decrease in platelets and erythrocytes and a subnormal concentration of pigment.² It has been reported that after the administration of 150 mg of cevitamic acid in acute essential thrombopenia the bleeding ceased and there was an increase in thrombocytes.³ Cevitamic acid can be determined chemically, the time required for an assay for vitamin C has thereby been greatly shortened. As this substance can be detected and measured in tissues, its distribution and function can be followed with reasonable accuracy.

Jungblut and Zwemer⁴ have recently reported that diphtheria toxin is inactivated by vitamin C in vitro. Furthermore, cevitamic acid seems to be able to protect guinea-pigs against the fatal outcome of diphtheria intoxication. Animals given liberal amounts of cevi-

tamic acid were much less sensitive to small doses of the toxin as measured by the intracutaneous test. Similar studies of King and Menten⁵ have demonstrated the marked influence of vitamin C in promoting the resistance of guinea-pigs to diphtheria toxin. In their investigation, in which growth was one of the criteria used, it was shown that animals receiving a restricted amount of cevitamic acid, yet enough to prevent any outward signs of scurvy, nevertheless were unable to resist the effects of the toxin as were those fortified with a greater dose of vitamin C. These conclusions seem to indicate that cevitamic acid bears a relation to immunologic reactions. This may be associated with its chemical reaction with the toxin or with an effect on the resistance of the host organism, perhaps motivated through the chemical state of the tissues.

The apparent association of cevitamic acid with resistance to infection is in a way paradoxical. The conception of a foreign agent (bacteria) as the cause of disease was so firmly established through the work of Pasteur, Koch and others that the idea of a deficiency of a dietary essential as an etiologic factor did not receive serious attention until the beginning of the present century. The recent studies emphasize that these two factors may be closely allied in the struggle for maintenance of physiologic well being.

Current Comment

DEATH OF OVUM AND PREGNANCY TEST

The value of the biologic tests for pregnancy in determining intra-uterine viability is not yet established. In an attempt to solve this question Bishop¹ has summarized the results given by the test in a series of cases in which the date of fetal death could be determined clinically with some degree of certainty. The Friedman test was employed in the eleven cases of the series. In two instances the test was still positive six weeks after the death of the fetus. With these exceptions the test tends to become negative between ten and twenty-four days after intra-uterine death has taken place. The Aschheim-Zondek test, according to other reports, tends to remain positive even longer. The reason for this apparently lies in the greater sensitivity of infantile mice to pregnancy urine than that of adult rabbits. Evidence exists that the Aschheim-Zondek and Friedman tests depend primarily on the presence or absence of functional chorionic tissue rather than on the life or death of the ovum. Since, however, the main function of the placenta is to provide a means of nourishing the living embryo, it might be expected to become inactive on the death of that embryo. Practically, however, it is clear that there is no direct relation between the death of the ovum and the disappearance of gonadotropic substance from the urine.

¹ Bishop P M F *The Pregnancy Test in Relation to Death of the Ovum* *Lancet* 2 364 (Aug 17) 1935

Furthermore, the time after death of the ovum at which the placenta ceases to elaborate the gonadotropic hormone seems to vary considerably in individual cases and to be determined by no mechanism so far understood. The cases here investigated throw no fresh light on these factors

IMPROVED BUILDING FOR AMERICAN MEDICAL ASSOCIATION

As was noted in the minutes of the Board of Trustees, published recently in *THE JOURNAL*, visitors to Chicago will see next year a striking improvement in the headquarters office of the American Medical Association. The changes contemplated include the addition of two stories and a roof assembly hall as additional structure, a re-finishing of the exterior of the building in limestone, and many other improvements in the arrangement and equipment of the various bureaus and headquarters offices. The changes are made necessary by the vast increase in the amount of work carried on by the headquarters office in recent years and with a view to still further demands in the future. The Association is now publishing many special periodicals in addition to *THE JOURNAL*, *Hygeia* and the *Quarterly Cumulative Index Medicus*, applications from additional specialties await opportunity to take over periodicals in these fields. The increasing demands on the councils that investigate and classify drugs, foods, educational activities, laboratories and other medical materials and functions are finding greater demands made on them every year. The Bureau of Legal Medicine and Medical Legislation finds its work greatly increased, and the growth of the Association indicates considerable expansion necessary in the Secretary's office. Moreover, the Bureau of Health and Public Instruction and the Bureau of Medical Economics have multiplied their work from three to five times in the last two years. These facts prompted the Board of Trustees to undertake the improvements that have been mentioned. Again and again the question was raised as to whether or not the Association ought to buy additional land and arrange for building a new structure at some other site or on the same site. In view of the exigencies of the present economic situation and the nature of the organization of the Association, the Board of Trustees considered it far more advisable to make a contract for immediate improvements in the present building. It is hoped that

visitors to Chicago in the future will avail themselves of the opportunity to observe the improved headquarters office in action

BOONDOGLING WITH A HEALTH SURVEY IN NEW YORK

Among the peculiar projects proposed by the WPA in New York State is one that has aroused the wrath and ridicule of a good many people. It was proposed to survey the deaf children in the county of Monroe at an estimated cost of \$10,440, Monroe County to pay \$1,390. In opposition to the survey, the Subcommittee on Deafness and Hard of Hearing of the Public Health Committee of the Medical Society of the County of Monroe offers the statement that it is impossible

to detect deaf children before the age of 3 years. The public and special schools take these children over at 5 years of age. Therefore, the whole project is limited to children between the ages of 3 and 5 years. There is good evidence that the county of Monroe contains several of these children. Evidence from the headquarters of the bureau for handicapped children in the New York State Education Department at Albany accounts for only fourteen such children, exclusive of those already cared for. Hence it is proposed to spend \$10,440 to survey fourteen children.¹ Furthermore, the survey proposes subsequent training of the deaf child but the project makes no provision for such training. If ever a project was

Proposed reconstruction of headquarters office.

developed to which the word boondoggling could quite certainly be applied, this project qualifies

PLACARDING INFECTIOUS DISEASES

The commissioner of health of the village of White Fish Bay, Wis., Edwin B. Gute, has designed an interesting new type of placard for the infectious diseases. For such infectious conditions as mumps, German measles, chickenpox, whooping cough and measles, placards have been developed which include not only a sign to be placed on the front and back doors of the house but also a card to be hung in the home containing information and advice to the members of the family on each of the conditions concerned. The cards describe not only the early signs and symptoms, the incubation period and the period of communicability but also the regulations regarding attendance at school.

¹ Boondoggling editorial. *New York State J. Med.* 35:1106 (Nov 1935)

and the conduct of the family during the period of illness. In addition, the card includes care of the sick-room, disinfection, and general information to the parents concerning the disease. The placard, which was recently exhibited at the meeting of the American Public Health Association, has attracted wide general attention and is likely to be adopted in other parts of the country.

Association News

RADIO BROADCASTS

The American Medical Association broadcasts over the Blue network and certain additional stations of the National Broadcasting Company at 5 p. m. eastern standard time (4 o'clock central standard time, 3 o'clock mountain time, 2 o'clock Pacific time) each Tuesday, presenting a dramatized program with incidental music under the general theme of "Medical Emergencies and How They Are Met." The title of the program is "Your Health." The program is recognizable by a musical salutation through which the voice of the announcer offers a toast "Ladies and gentlemen, your health!" The theme of the program is repeated each week in the opening announcement, which informs the listener that the same medical knowledge and the same doctors that are mobilized for the meeting of grave medical emergencies are available in every community, day and night, for the promotion of the health of the people. Each program will include a brief talk dealing with the central theme of the individual broadcast.

The next three programs are as follows:

| | | |
|-------------|------------------------------|----------------------|
| November 19 | Infection | Morris Fishbein M.D. |
| November 26 | Common Household Emergencies | W. W. Bauer M.D. |
| December 3 | Tuberculosis | Morris Fishbein M.D. |

This program is broadcast also on the short waves through KDKA, Pittsburgh, over station W8XK, 11,870 and 12,210 kilocycles.

Medical News

(PHYSICIANS WILL CONFER A FAVOR BY SENDING FOR THIS DEPARTMENT ITEMS OF NEWS OF MORE OR LESS GENERAL INTEREST SUCH AS RELATE TO SOCIETY ACTIVITIES, NEW HOSPITALS, EDUCATION, PUBLIC HEALTH, ETC.)

ALABAMA

Another Full Time Health Unit—The establishment of the Henry County Health Department on a full time basis brings the total number of these full time units in the state to fifty-six. The new unit will begin functioning January 1. An effort is being made to place all county health departments on a full time basis.

Regional Headquarters for National Health Survey—Willis C. Beasley, A.M., formerly instructor in psychology, Johns Hopkins University, Baltimore, is in Alabama establishing headquarters for four states now being studied in the national survey of health conducted by the U. S. Public Health Service. Montgomery has been designated regional headquarters for Alabama, Georgia, Louisiana and Texas. In Alabama the study will be carried on at Montgomery, Birmingham, Anniston, Eufaula and Greenville.

CALIFORNIA

Examiners Reelect Officers—At a meeting of the state board of medical examiners in Sacramento, October 21, Dr. William R. Molony, Sr., Los Angeles, was reelected president, Dr. Clark L. Abbott, Oakland, vice president, and Dr. Charles B. Pinkham, San Francisco, secretary.

Semiannual Medical Meeting—The Southern California Medical Association will hold its ninety-third semiannual meeting at the Los Angeles County Medical Building, November 29-30. Guest speakers will be Drs. Edwin E. Osgood, assistant professor of biochemistry and medicine, University of Oregon,

Medical School and George Gill Richards, Salt Lake City, Utah. Other speakers will include:

- Dr. Harold L. Thompson, Los Angeles, Perforated Peptic Ulcer.
- Dr. Joseph Salem Rubin, Los Angeles, Bilateral Spermatocoele with Report.
- Dr. Wilbur P. Bailey, Los Angeles, Usual and Unusual Manifestations of Hodgkin's Disease.
- Dr. John Luther Maroon, Santa Ana, Subacute Bacterial Endocarditis.
- Dr. Edward C. Pallette, Los Angeles, Portal Thrombosis.
- Dr. Milo K. Tedstrom, Santa Ana, Spontaneous Hypoglycemia with Especial Reference to Cardiac Symptoms.

Society News—Dr. Neil Hamilton Fairley, secretary, Royal Society of Tropical Medicine and Hygiene, London, addressed the San Francisco County Medical Society, November 13, on "Present-Day Ideas of Blackwater Fever in Relation to Malaria." A discussion of the Ceylon malaria epidemic was included. Speakers before the society, November 12, included Drs. Fred H. Kruse on "Medical Aspects of Esophageal Disorders", Thomas F. Mullen, "Surgical Treatment of Benign Stricture of the Esophagus", and Montague S. Woolf, "Benign Fibrous Stricture of the Rectum (Lymphogranuloma Inguinale)". Dr. Ben L. Bryant, Cincinnati, among others, will address the section on eye, ear, nose and throat, November 26, on "Hypothyroidism in the Practice of Otorhinolaryngology."

University News—The Northern California Alumni Association of the College of Medical Evangelists was addressed at its semiannual meeting in San Francisco, October 27, by Drs. George V. Kulchar on "Clinical Management of Syphilis", George D. Barnett, "Cardiac Problems as seen by the General Practitioner", Leroy C. Abbott, "Skeletal Traction in Fractures of the Long Bones, and Especially of the Shaft of the Femur", and Edmund W. Butler, "Diagnosis of the Acutely Shocked Patient."—The annual Alumni Day of the University of California School of Medicine, San Francisco, will be observed, November 22. The day will be devoted to the reading of papers, clinics and conferences. Dr. John C. Ruddock, Los Angeles, class of 1916, will deliver the annual Alpha Omega Alpha lecture in the late afternoon.

DISTRICT OF COLUMBIA

University News—Major Gen. Charles R. Reynolds, surgeon general, U. S. Army, gave the first lecture in the Smith-Reed-Russell series at George Washington University School of Medicine, October 24. The title of his address was "The Medical Corps of the United States Army."

Tuberculosis Campaign with WPA Funds—With \$99,000 available from the Works Progress Administration, a campaign to eradicate tuberculosis in the District of Columbia will begin, November 25. X-ray machines will be placed at strategic positions in the city to take roentgenograms by means of the paper method. Physicians may refer patients either for an initial film or for a check on a patient under treatment. All the work will be done without cost to the patient. A special effort will be made to investigate persons in homes where recognized cases exist. The Medical Society of the District of Columbia is cooperating in the drive.

Society News—Dr. Claude S. Beck, associate professor of medicine, Western Reserve University School of Medicine, Cleveland, will address a joint meeting of the Medical Society of the District of Columbia and the Washington Heart Association, November 20, on "The Heart as a Surgical Organ."—Dr. Grace G. Purse, Washington, discussed pernicious anemia before the Women's Medical Society of the District of Columbia, November 5.—Dr. Walter Timme, New York, discussed "Status Hypoplasticus", with its involvement of the Internal Glandular Mechanisms, before the naval medical officers of the District of Columbia at their first regular monthly meeting, October 7. Dr. Oswald S. Lowinsky, New York, discussed "New and Improved Developments in Urologic Surgery" at the meeting, November 4.

ILLINOIS

Personal—Dr. Maskell Lee, Atlanta, observed his eightieth birthday with a dinner, October 17.—Dr. Walter H. Baer has been appointed managing officer of the Peoria State Hospital.

Meeting of Bacteriologists—The first annual meeting of the Society of Illinois Bacteriologists was held at the Chicago Woman's Club, Chicago, November 1. Fred W. Tanner, Ph.D., Urbana, president of the society, opened the meeting. Dr. Alexander A. Day, chairman, department of bacteriology, Northwestern University Medical School, Chicago, spoke on "Trends of Medical Bacteriology", A. L. Whiting, Urbana, "High Points of Agricultural Bacteriology", and Winford Lee Lewis, Ph.D., director, scientific research, Institute of American Meat Packers, Chicago, "What Bacteriology Means to Industry." The society was organized May 8.

Chicago

Physicians Invited to History Lectures—Physicians are cordially invited to attend a course of lectures on the history of medicine at the University of Illinois College of Medicine. Dr Morris Fishbein, editor of THE JOURNAL is lecturing every Monday through the semester from 5 to 6 o'clock.

Hospital News—Construction has begun on a new \$75,000 two story addition to Michael Reese Hospital. The first floor and basement of the new building will be occupied by a medical library, given by Louis Florsheim in memory of his wife, Lillian. The Samuel Deutsch Human Convalescent Serum Center will be on the second floor. The center prepares human serum mainly for infantile paralysis, scarlet fever and measles.

University News—Dr Charles W Hughes, assistant in anatomy at Loyola University School of Medicine, has been appointed associate professor of anatomy, succeeding Dr Simon B Chandler. Forty-nine students in the school of medicine were awarded certificates of membership in honorary seminars, October 14. Membership in the seminars is restricted to students of high scholastic standing who are in a position to handle difficult diagnosis, technic and treatment of cases presented for discussion at seminar meetings. Of ten clinics now operating in the Loyola University Dispensary, the allergy clinic is the most frequented, it is reported.

INDIANA

Society News—Dr Homer H Wheeler will discuss diseases of the anorectal region before the Indianapolis Medical Society, November 19, Dr Julius H P Gauss, jaundice, its significance and implication, and Dr Walter Stoeffler, intussusception. The society held a joint meeting with the Seventh District Medical Society, November 12, at which Dr Paul D White, Boston, discussed various phases of heart disease. Dr George J Garceau talked on backache before the Indianapolis Medical Society, November 5.

Personal—Dr Dunn Hamilton Row, Indianapolis, sailed, November 1, for Shikarpur, Baluchistan, India, where, with four other eye specialists, he will conduct an eye clinic.—Dr James E McMeel, South Bend, has been made medical supervisor and director of Notre Dame University, succeeding the late Dr Francis J Powers.—Dr Charles C Holland has been appointed health officer of Bloomington, succeeding Dr Russell A De Motte.—Dr Holger M Andersen, formerly on the staff of the Epworth Hospital, South Bend, has been appointed to the medical staff of Culver Military Academy, Culver.

IOWA

Personal—Dr Fred H Howard, Strawberry Point, was guest of honor at a banquet, October 14, in celebration of his completion of fifty years' practice in the community.—Dr Charles F Schilling, Takoma Park, Md., has been appointed medical director of Iowa Sanatorium and Hospital, Nevada, succeeding the late Dr John F Morse.

Society News—A symposium on unusual goiter problems was presented before the Des Moines Academy of Medicine and Polk County Medical Society, November 12, by Drs Ben F Kilgore, John B Synhorst and Harry A Collins. A symposium on appendicitis was presented at the meeting, October 29, by Drs Bernard C Barnes, Earl D McClean, Harold N Anderson and William E Sanders.

KENTUCKY

Society News—At a meeting of the Northeastern Kentucky Medical Association in Paintsville, October 17, speakers were Drs Ray M Bobbitt, Huntington, W Va., on "Management of Infections of the Urinary Tract", Samuel C Smith, Ashland, "Why We Should Belong to and Attend Medical Organizations", Samuel Overstreet, Louisville, "Significance and Treatment of Upper Abdominal Pain", Albert L Bass, Louisville, "Ciliary Action of Respiratory Epithelium," and Philip F Barbour, Louisville, "Anorexia of Children, Cause and Treatment".—A symposium on poliomyelitis was presented at a meeting of the Jefferson County Medical Society, Louisville, November 4, by Drs Hugh R Leavell, Aura J Miller, William W Nicholson and Richard T Hudson. In a symposium on anemia, November 18, speakers will be Drs William H Allen, Arthur T Hurst and Edward C Humphrey.—Dr Aura Jones Miller addressed the Louisville Medical-Chirurgical Society, November 8, on "Present-Day Problems in Typhoid Fever".—Dr Owsley Grant addressed the Louisville Surgical Society, November 1, on "Infectious Surgical Conditions of the Kidney".—Dr Frank A Simon presented a paper on "Hypersensitiveness to Pituitary Extracts" and Dr Arthur T Hurst on "Treatment of Anemia" at a meeting of the Transylvania Medical Society, Louisville, November 7.

MAINE

Society News—The Washington County Medical Society was addressed in Calais recently by Drs Reginald L Cameron, Eastport, on health problems in Washington County, and Norman E Cobb, Calais, "Craniorachischisis Type of Fetal Monstrosities".

MARYLAND

Society News—At a meeting of the Society of Hygiene of Johns Hopkins University, October 23, in Baltimore, speakers were Janet H Clark, Ph D, on "Effect of Ultraviolet Radiation on Lens Protein and the Relation of Radiation to Industrial and Senile Cataract," and Raymond Pearl, LL.D., "Incidence of Tuberculosis Among the Offspring of Tuberculous Parents".

Attendance of Midwives at Births Decline—Of 27,317 births recorded in Maryland in 1934, 90 per cent were attended by physicians and 10 per cent by midwives. According to the state department of health, the records of the bureau of vital statistics show a decline in the attendance of midwives at births since 1916, when the state was admitted to the birth registration area. In Baltimore the attendance of physicians at white births increased from 67.3 per cent of the total in 1916 to 95.1 per cent in 1934. The attendance of physicians at Negro births increased from 76.2 per cent of the total in 1916 to 92.9 per cent in 1934. There were 2,617 physicians practicing in the state in 1934, 872 in the counties and 1,745 in Baltimore. There were 313 midwives, 244 in the counties and sixty-nine in Baltimore.

MASSACHUSETTS

Clinical Lectures—Dr Siegfried Thannhauser, formerly director of the medical clinic and professor of internal medicine at the University of Freiburg in Bremen and now associate professor of medicine at Tufts College Medical School, Boston, opened a series of clinical lectures at the Boston Dispensary, November 2, with a talk on diabetes. November 9 he also spoke on diabetes. He is giving a lecture on liver disease, November 16, and on November 23 will discuss peptic ulcer.

Dr Houssay Gives Dunham Lectures—Dr Bernardo A. Houssay, professor of physiology and director of the Institute of Physiology, University of Buenos Aires, will deliver three lectures under the Edward K. Dunham Lectureship for the Promotion of the Medical Sciences, on "Recent Studies on the Functions of the Hypophysis". The lectures will be given at the Harvard Medical School, November 22, on "What We Have Learned from the Toad Concerning Hypophyseal Functions", November 25, "Metabolic Functions of the Hypophysis," and November 27, "The Hypophysis and Diabetes". The lectureship was founded in 1923 in honor of Dr Dunham, who graduated from Harvard in 1886, it is given annually.

MICHIGAN

Commission on Medical Economics—The Medical Economics Commission of the Wayne County Medical Society was recently formed to initiate and coordinate studies and investigations in the field of medical economics and recommend policies of medical, hospital and public health practice and medicocivic relations to the council of the society. The former committees on public health, medicocivic relations, industrial relations and unauthorized practice of medicine have been merged into the medical economics commission as four of its six sections. The section on lay cooperation will study the any encroachment of lay workers in the professional field, the work of school nurses and laboratory technicians, plans of sickness insurance will be investigated and a program of public information to secure lay cooperation will be developed. The section on public health relations will study and develop cooperation with health departments and with the officials of the Emergency Relief and Works Progress Administrations in providing medical service to relief clients. It will aid the local medical school in any necessary modification of its curriculum. The section on coordination of medical services will study hospital and dispensary economics and reported abuses, medical representation on hospital boards, hospital staff cooperation, relations between hospitals and physicians, social service departments including intake policy, pay clinics and diagnostic clinics and nurse anesthetists. Counter prescribing and other drug store abuses will be studied by the section on coordination of pharmaceutical service. It will also recommend ways of cooperation with ethical pharmacists. The section on legislation in relation to medical economics will study bills and proposals for presentation to the Michigan legislature and to Congress to aid the physician. The work of the section on industrial relations will deal with workmen's compensation, contract prac

tice, the activities of insurance companies and industrial plants in the medical field and the relation of industry in general to the physician. Dr Frank W Stafford is chairman of the new commission

MINNESOTA

Dr Cottam Named Director of Health of Minneapolis—Dr Gilbert G Cottam was recently appointed to the newly created position of director of health and hospitals for Minneapolis. The new position has jurisdiction over the Minneapolis General Hospital and the city health department, it was stated. Dr Cottam was graduated from Marion-Sims Medical College, St Louis, in 1893.

University Courses—A night course in preventive medicine was opened, October 3, by the extension division of the University of Minnesota, Minneapolis. It will continue for seventeen weeks under the direction of Dr Harold S Diehl, dean of medical sciences. A course in tuberculosis and other diseases of the chest by Dr Jay Arthur Myers is given the same evening following the course in preventive medicine.

Society News—Dr Frederick H K Schaaf, Minneapolis, among others, addressed the Renville County Medical Society in Olivia, recently, on "Advances in Therapeutics"—The St. Paul Surgical Society has been organized with Drs Harry B Zimmermann as president, Elmer M Jones, vice president, and Nathaniel L Leven, secretary—At a meeting of the Minnesota Academy of Medicine in Minneapolis, November 13, theses were presented by Drs Robert G Allison, Minneapolis, and Lyle C Bacon, St. Paul, entitled "Radiation Therapy" and "Schlatter's Disease," respectively.

MISSOURI

Personal—Dr John R Bruce, Marshfield, has been appointed health commissioner of Webster County; he formerly served as county physician—Dr Charles W Burrill observed his ninetieth birthday at his home in Kansas City October 20. Dr Burrill graduated from Northwestern University Medical School in 1872 and has been a member of the Jackson County Medical Society since 1883.

NEW HAMPSHIRE

Dr Bielschowsky at Dartmouth—Dr Alfred A Bielschowsky, formerly professor of ophthalmology at the University of Breslau Germany, who spent six months last year at Dartmouth Medical School, Hanover, doing special research in physiologic optics, has now joined the faculty as visiting lecturer in ophthalmology, Science reports. Dr Bielschowsky was at the University of Breslau for about ten years and had previously been on the faculties of the Universities of Marburg and Leipzig.

NEW YORK

Society News—Dr Pol N Coryllos, New York, addressed the Broome County Medical Society, Binghamton, November 5 on empyema—Dr Bret Ratner, New York, addressed the Schenectady County Medical Society, Schenectady, November 5 on "The Problem of Allergy in Childhood"—Dr Jane Sands Robb addressed the Onondaga Medical Society Syracuse, November 5, on "Studies of the Physiology of Cardiac Conduction"—Drs William A Groat and Tyree C Wyatt reported a case of acute basophilic leukemia.

Dr Pinner Appointed Pathologist—Dr Max Pinner, Tucson, Ariz, has been appointed principal diagnostic pathologist for the state tuberculosis hospitals of New York with headquarters at the Biggs Memorial Hospital, Ithaca. Dr Pinner received his medical education at the Universities of Tübingen and Berlin, Germany. Before going to Tucson he was engaged in research at the Municipal Tuberculosis Sanatorium in Chicago and later was director of laboratories at the Maybury Sanatorium, Northville, Mich and pathologist at the Herman Kiefer Hospital Detroit.

Study of Maternal Mortality—The Medical Society of the County of Erie is making a study through its maternal mortality survey committee, of maternal deaths. From January 1 to June 1, thirty-two deaths were studied with special reference to the preventability of the death and where the responsibility lay. Supplemental obstetric information is obtained from special sheets sent out with birth certificates from the Buffalo health department from this information a study will be made of types of delivery. Obstetric nursing is also being considered in the survey and a program of public educational work is being carried on in cooperation with the local child health week committee. The survey committee asks the cooperation of physicians, families and medical examiners in obtaining necropsies on every maternal death.

New York City

Brickner Lecture—Dr David Marine will deliver the fifth Walter M Brickner Lecture of the Hospital for Joint Diseases, November 21, at the hospital. Dr Marine's subject will be "Some Practical Aspects of Thyroid Physiology."

Second Harvey Lecture—Robert M Yerkes, Sc D, professor of psychobiology, Yale University School of Medicine, New Haven, will deliver the second Harvey Lecture of the winter at the New York Academy of Medicine November 21. The title of the lecture will be "The Significance of Chimpanzee-Culture for Biological Research."

Personal—Dr Thomas A Martin, medical director of Harlem Hospital, has been made director of medical services at Saint Vincent's Hospital—Dr August W F Westhoff has been appointed chief of the medical staff of Wyckoff Heights Hospital. Members of the staff entertained Dr Westhoff at dinner to mark the event and presented him with a gold watch.

Clinical Meeting of Diabetes Association—The first meeting of the clinical section of the New York Diabetes Association was held, November 15, at New York University College of Medicine. Speakers were Louis I Dublin, Ph D, on "Statistics of Diabetes in the United States", Dr Herman O Mosenthal, "The New York Diabetes Association", F W Nordsiek, executive secretary of the association, "Survey of Diabetic Clinics in New York City," and Dr Charles F Bolduan, "Diabetes—A Health Problem in New York City."

Twenty Thousand Warnings—New York's campaign against unnecessary noise entered its second phase, November 1, when the ban on noise, first applied only at night during October was extended to include the day as well. Police were instructed to warn all persons who caused noises they could have avoided by being considerate. Typical instances included the unnecessary sounding of horns by motorists trying to blast their way through traffic, loud radios either in automobiles or in homes attempting to call persons to windows by blowing horns, unnecessary racing of motors, workers congregating in front of establishments talking in loud tones at night, truck deliveries with undue noise, persons returning home in groups singing or talking loudly, cut outs open on motorcycles, or trucks or vehicles with mufflers functioning badly, operators of cabarets, restaurants and dance halls in residential neighborhoods permitting loud music at unreasonable hours, and patrons of these places leaving at closing times using loud and boisterous language. During October the police issued 20,334 warnings and 172 summonses to noise offenders. Mayor La Guardia reported that notable progress had been made.

NORTH CAROLINA

Personal—Dr Ransom L Carr, Rose Hill, has been appointed health officer of Duplin County to succeed Dr Clarence H White, Kenansville, resigned.

Society News—Dr Olin B Chamberlain, Charleston S C, was guest speaker at the fall meeting of the Tenth District Medical Society in Tryon October 16, his subject was "Anemia and the Nervous System." Other speakers were Drs Paul T McBee, Marion, on peptic ulcer, John C Young, Asheville, genito-urinary diseases, Roy H Moore, Canton, blood transfusion, and Cecil C Swann, Asheville, sinus disease and chronic conditions of the chest—Dr Harold S Clark, Asheville, addressed the Buncombe County Medical Society, Asheville, October 7 on "Acute Virulent Infections of the Hand"—Dr Edwin A Merritt, Washington D C, addressed the Wayne Medical Society, Goldsboro, October 4, on radiotherapy in treatment of tumors and cancer.

OHIO

Personal—Dr Herbert D Chamberlain, McArthur, has been appointed health commissioner in charge of a new health unit in Vinton County—Dr Fred G Carter superintendent of the Ancker Hospital St Paul, has been placed in charge of Christ Hospital, Cincinnati.

Annual Health Conference—The sixteenth annual conference of health commissioners with the state department of health was held in Columbus November 13-15. Guest speakers were Drs Jay Arthur Myers, Minneapolis, on tuberculosis, Eugene L Bishop, Knoxville, Tenn, on health and sanitation in the Tennessee Valley, Martha M Eliot, Washington, D C, maternal and child health, John Collinson, U S Bureau of the Census, Washington, vital statistics, and James A Doull, Cleveland a survey of the state health department.

New Huron Road Hospital—A new building for the Huron Road Hospital, Cleveland with an eventual capacity of 300 beds, was recently opened. The building is six stories high.

and is arranged in three wings, one of which is used for a nurses' home at present. The two wings forming the front of the building provide 200 beds. Five floors are devoted to regular service, on the fifth is a nursery, and the operating suite is on the sixth. There are no wards as such. Each room unit consists of two semiprivate two-bed rooms separated by a service area. On the ground floor are the outpatient department, dining rooms and kitchen, the pharmacy and the physical therapy department.

Society News—Dr. Homer F. Swift of the Rockefeller Institute for Medical Research, New York, addressed the Cleveland Academy of Medicine, November 15, on rheumatic fever. Major Gen. Charles R. Reynolds, surgeon general of the U. S. Army, addressed a special meeting of the military medicine section of the academy, November 6, on "The Employment of the Medical Profession in Time of a National Emergency."—Dr. Henri Coutard, chief of service of roentgenology, Curie Institute, University of Paris, gave a lecture on radiation therapy at the University of Cincinnati, October 11, under the auspices of the university and the Cincinnati Cancer Control Clinic.—Dr. Edward C. Rosenow, Rochester, Minn., addressed the annual joint meeting of the Toledo Academy of Medicine and the Toledo Dental Society, November 1, on "Focal Infection and Elective Localization of Bacteria."

PENNSYLVANIA

Personal—The trustees and staff of Allentown Hospital gave a testimonial dinner in honor of Dr. Robert L. Schaeffer, chief surgeon at the hospital, October 31, celebrating the twenty-fifth anniversary of his association with the institution.

Society News—Drs. William Bates and Robert H. Ivy, Philadelphia, conducted the fall clinic of the Locomotor County Medical Society, Williamsport, November 8. Dr. Bates discussed "Back Sprains—First Lumbar Neuralgia" and Dr. Ivy "Maxillofacial Surgery."—Drs. Ralph P. Beatty, Uniontown, and Harry J. Bell, Dawson, addressed the Fayette County Medical Society, Uniontown, November 7, on "Prostatic Obstruction" and "The Art of Prognosis," respectively.

Hospital News—A campaign for funds for the Warren General Hospital, Warren, resulted in raising \$56,000, which was \$11,000 more than the amount sought. Physicians subscribed \$1,800, it is reported.—The first annual meeting of the Association of Resident and Ex-Resident Physicians of the George F. Geisinger Memorial Hospital, Danville, was held October 25-26. Drs. Harold L. Foss and Carl L. Evin conducted surgical and medical clinics and members of the association presented papers. Dr. Henry K. Seelaus, Philadelphia, was elected president.

Philadelphia

Society News—Speakers before the Philadelphia Academy of Surgery, November 4, were Drs. William R. Gilmour, on "Gas Gangrene in Civil Practice", John W. Klopp, "Tetanus: Experience of the Episcopal Hospital in the Past Thirty Years" and Ralph S. Bromer, "X-Ray Treatment of Acute Infections."—At a meeting of the Philadelphia Laryngological Association, November 5, speakers were Drs. Samuel Cohen, on "Present Status of Rhinoplastic Surgery", Matthew S. Ersner, "Amputation of the Nose, Corrected by Various Forms of Prostheses," and George W. MacKenzie, "Nystagmus."—Edgar A. Doll, Ph.D., Vineland, N. J., and Dr. Bronson Crothers, Boston, addressed the Obstetrical Society of Philadelphia, November 7, on "The Behavioral Consequences of Birth Injuries" and "The Validity of the Diagnosis of Birth Injury After the Neonatal Period," respectively.—Drs. Eldridge L. Eliason and Lewis K. Ferguson addressed the Philadelphia Roentgen Ray Society, November 7, on "Intestinal Obstruction" and "Epiphyseal Separation," respectively.

SOUTH CAROLINA

Founders Day at Medical College—Dr. David Riesman, Philadelphia, delivered the Founders Day lecture at the annual celebration of the Medical College of the State of South Carolina, November 13. Dr. Riesman's subject was "The Clinical Approach." During the day members of the faculty conducted clinics on various subjects and Dr. Riesman conducted a medical clinic in the afternoon. The occasion was the one hundred and eleventh anniversary of the opening of the college.

Society News—At a meeting of the Fourth District Medical Association, Gaffney, October 15, speakers included Drs. John R. Harrison, Greer, on "Infections of the Upper Respiratory Tract", Everett B. Poole, Greenville, "Physiologic Factors in the Production of the Allergic State," and William McNeill Carpenter, Greenville, "What the General Practitioner Should Know About Glaucoma."—Speakers at a meeting of the

Third District Medical Association, October 18, included Drs. Abraham Ellis Poliakoff, Abbeville, on "Treatment of Nephritis", William S. Judy, Greenville, "Treatment of Certain Endocrine Disorders," and George R. Wilkinson, Greenville, "Principal Cause of Backache in the Latter Half of Life."—Dr. Grady S. Clinkscales, Anderson, presented a paper on artificial pneumothorax at a meeting of the Anderson County Medical Society, Anderson, October 9.—Dr. Kenneth M. Lynch, Charleston, addressed the Columbia Medical Society, October 14, on cancer of the liver.

TENNESSEE

Health at Nashville—Telegraphic reports to the U. S. Department of Commerce from eighty-six cities with a total population of 37 million indicate that the highest mortality rate (21.4) for the week ended November 2 appeared for Nashville and that the rate for the group of cities was 10.9. The mortality rate for the corresponding week of 1934 was 15.8 for Nashville and 10.6 for the group of cities. The annual rate for the eighty-six cities was 11.3 for the forty-four weeks of 1935 and the same rate appeared for the corresponding period of the previous year. Caution should be used in the interpretation of these weekly figures, as they fluctuate widely. The fact that some cities are hospital centers for large areas outside the city limits or that they have a large Negro population may tend to increase the death rate.

TEXAS

Society News—A symposium on medical economics will be presented at a meeting of the Dallas County Medical Society, November 27, by Drs. Holman Taylor, Fort Worth, Martin L. Wilbanks, Greenville, Texas, John H. Burleson, San Antonio, and Oscar M. Marchman, Dallas. Drs. John R. Lehmann and James T. Mills, Dallas, addressed the society, October 24, on "The Marijuana Menace" and "Treatment of X-Ray Burns," respectively.

Relief Agreement Terminated—The Texas State Medical Association terminated its agreement with the Texas Relief Commission governing emergency medical relief, October 1. Any further service of this kind will be carried on through agreements between county medical societies and county relief administrations, the state medical journal announces. Under the arrangement the state association made no contracts, the journal points out, but agreed to foster contracts of the county societies and to serve as a board of adjustment. The whole affair has been a service, and the majority of those who have served under these contracts have done so at a loss and with no little discomfort. On the whole, it was conducted effectively both on the part of the medical society and on the part of the relief commission, the editorial concludes.

VIRGINIA

State Medical Election—Dr. James Morrison Hutcheson, Richmond, was chosen president-elect and Dr. Philip St. Leger Moncre, Norfolk, was installed as president of the Medical Society of Virginia at the annual meeting in Norfolk, October 15-17. Vice presidents elected are Drs. Charles Lydon Harrell, Norfolk, Edmund M. Chitwood, Wytheville, and John A. Owen, Turbeville. Miss Agnes Edwards was reelected executive secretary and treasurer.

Personal—Dr. William Grossmann Jr., Petersburg, has been appointed assistant epidemiologist in the state department of health.—Dr. Shockley D. Gardner, South Boston, has been appointed health officer of the Valley Health District, with headquarters in Harrisonburg.—Dr. James N. Dudley, Danville, has been appointed director of the Henrico County Health District with headquarters in Richmond.—Dr. Thomas B. Payne has been appointed health officer of Fredericksburg to succeed the late Dr. Justus Lee Cooke.

Centennial of Dr. Hunter McGuire—The one hundredth anniversary of the birth of Dr. Hunter Holmes McGuire, distinguished Virginia surgeon, was celebrated by a ceremony in Richmond, October 11. William T. Sanger, LL.D., president of the Medical College of Virginia, presided at the exercises, which were held at Dr. McGuire's monument in Capitol Square. Speakers were Gov. George C. Peery, Drs. Marshall J. Payne, Staunton, and W. Lowndes Peple, Richmond, former students of Dr. McGuire, and Col. Robert T. Barton Jr., son of an intimate friend of Dr. McGuire. During the Civil War Dr. McGuire was medical director of the Army of the Shenandoah under the command of Stonewall Jackson, later surgeon to the Second Army Corps and medical director of the Army of Northern Virginia. After the close of the war he was for several years professor of surgery at the Medical College of Virginia. In 1893 he was instrumental in the founding of

the University College of Medicine and the Virginia Hospital and was president of both institutions. He was also professor of surgery. He was one of the founders of the Medical Society of Virginia of which he was president in 1880-1881. He was president of the American Surgical Association in 1886 and of the American Medical Association in 1893. He died Sept. 19, 1900.

WEST VIRGINIA

Society News—Dr. William J. Engel, Cleveland, addressed the Cabell County Medical Society, Huntington, October 10 on "Diagnosis and Treatment of Cystitis in the Female." At a joint meeting of the Harrison, Monongalia and Marion county medical societies in Clarksburg, October 3, Drs. Harvey G. Beck and Albert E. Goldstein, Baltimore spoke on "Chronic Carbon Monoxide Anoxemia" and "Nephralgia—Symptomatology, Diagnosis and Treatment," respectively. Dr. John A. Kolmer, Philadelphia, addressed the Fayette County Medical Society, Montgomery, October 17, on "Infection, Immunity and Vaccination in Infantile Paralysis." Dr. Vincent V. Smith, Ironton, Ohio, discussed "Injection Treatment of Hemorrhoids" before the Logan County Medical Society, Logan, October 16. At a meeting of the Greenbrier Valley Medical Society, Roncove, October 15, Drs. Andrew E. Amick and William P. Black, Charleston, spoke on infant feeding and treatment of hemorrhoids, respectively.

GENERAL

Award for Exhibit of Diagnostic Tests—The U. S. Public Health Service and the American Society of Clinical Pathologists were awarded a certificate of merit for an exhibit on the evaluation of serodiagnostic tests for syphilis. A preliminary article describing the study now in progress on this subject appeared in THE JOURNAL, June 8, page 2083.

Search for Szent Norager—The Minnesota State Board of Medical Examiners is attempting to find one Szent Norager, who has used the aliases Dr. James Edw. Petri and Dr. E. Mendoza. This man is of Danish descent, is between 35 and 40 years of age, and speaks English brokenly. He has represented himself in Minneapolis as being a doctor of medicine. Within the past year he has lived at the following addresses in Minneapolis: 1110 Ulysses Street, N. E., 4008 Thirty-Seventh Avenue, S., and 3863 Minnehaha Avenue. His present whereabouts are unknown. He has been represented as a "patent medicine" salesman and a fortune teller. Any information about this person will be appreciated by the Minnesota State Board of Medical Examiners, St. Paul.

National Academy of Sciences—At the autumn meeting of the National Academy of Sciences at the University of Virginia, University, November 18-20, speakers will include:

Dr. Charles R. Stockard, New York: Giant Skin Growth on Mammals with Normal Sized Skeletons.
Dr. William H. Howell, Baltimore: The Production of Blood Platelets in the Lungs.
Dr. David I. Macht, Baltimore: Experimental and Clinical Study of Cobra Venom as an Analgesic.
Lyndon F. Small, Ph.D., University Va.: Studies of New Narcotics.
Carl C. Speidel, Ph.D., University Va.: Effects of Alcohol on Nerves in Living Frog Tadpoles.
Yandell Henderson, Ph.D., New Haven, Conn.: How Cars Go Out of Control: Analysis of the Driver's Reflexes.

Nearly Nine Thousand Cases of Poliomyelitis—While the number of cases of poliomyelitis reported this year is in excess of those reported for earlier years, the disease is on the decline at this time. According to *Public Health Reports* 8,884 cases were reported throughout the country for the twenty-four weeks ended October 12, as compared with 5,944 during the similar period in 1934, 3,862 in 1933 and 2,843 in 1932. In this period this year, 2,601 cases were reported in New York and 1,232 in Massachusetts. Last year during this period the greatest number of cases, 2,937, was recorded for California. The cases reported were 3,625 for the four weeks ended September 7 and 2,528 for the four weeks ended October 5. Poliomyelitis has been most prevalent in the regions along the Atlantic coast. The South Atlantic states continue to report a rather high incidence, and in some states in the East North Central and South Central regions the incidence was somewhat above the seasonal expectancy. In the Mountain and Pacific regions the number of cases was only about 20 per cent of last year's figures for the period ended October 5 but it was slightly above that for each of the three preceding years. The West North Central states reported about the normal incidence for this season.

Society News—At the fourth annual meeting of the Society of Plastic and Reconstructive Surgeons in Detroit, October 19, speakers were Drs. George M. Dorrance, Philadelphia on "Surgical Treatment of Different Varieties of Cleft Palate," Grover C. Penberthy, Detroit, "Treatment of Burns," John

M. Wheeler, New York, "Transplantation of the Human Cornea: Its Present Status," and George V. I. Brown, Milwaukee, "Restoration of Motion in Cases of Traumatic Facial Paralysis."—Dr. Charles A. Waters, Baltimore, was named president-elect of the American Roentgen Ray Society at its recent annual meeting in Atlantic City. Dr. Frederick M. Hodges, Richmond, was installed as president and Dr. Bernard H. Nichols, Cleveland, and Major John J. Moore, San Francisco were elected vice presidents. Dr. Eugene P. Pendergrass, Philadelphia, was reelected secretary. The 1936 meeting will be held in Cleveland.—Dr. Lemuel Whittington Gorham, Albany, N. Y., was elected president of the American Clinical and Climatological Association at its annual meeting in Princeton, N. J., October 21-23. Drs. Alvah H. Gordon, Montreal, and Chauncey W. Dowden, Louisville, Ky., were named vice presidents and Dr. Francis M. Rackemann, Boston, was reelected secretary.—Dr. Eugene H. Pool, New York, was chosen president-elect of the American College of Surgeons at the annual meeting in San Francisco, October 31. Dr. Donald C. Balfour, Rochester, Minn., was installed as president and Drs. Emile F. Holman, San Francisco, and George E. Wilson, Toronto, were elected vice presidents.—Dr. William C. Menninger, Topeka, was elected president of the Central Neuropsychiatric Hospital Association, which met in Topeka, October 26, in conjunction with the Central Neuropsychiatric Association. The next meeting will be in Chicago in March.

CANADA

Society News—The annual meeting of the British Columbia Medical Society was held in Vancouver recently. Speakers at the annual dinner were Drs. James Tate Mason, Seattle, President-Elect of the American Medical Association, on "Medicine and Social Progress" and George J. Wherrett, Ottawa, executive secretary of the Canadian Tuberculosis Association, "Progress of Tuberculosis Control in Canada."—Drs. George F. Strong and Alec M. Agnew addressed the Vancouver Medical Association, Vancouver, B. C., October 2, on "Cardiac Pain" and "Vaginal Plastic Surgery," respectively.

LATIN AMERICA

Appointed to Leprosy Center—Howard I. Cole, Ph.D., formerly chief chemist of the Culion Leper Colony, P. I., has been appointed by the League of Nations to conduct research at the new International Leprosy Center in Rio de Janeiro, according to *Science*.

Society News—The Medical Society of Mendoza, the Argentine Society of Regional Pathology of the North, dedicated its ninth meeting to Prof. Carlos Chagas, Rio de Janeiro, who died in December 1934. The session was held in Mendoza, October 1-3.—The third Pan-American Red Cross Conference was held in Rio de Janeiro, Brazil, recently.

FOREIGN

International Congress of Surgery in Cairo—The tenth International Congress of Surgery will be held in Cairo, Egypt, December 30 to January 4 under the presidency of Prof. Anton von Eiselsberg of Vienna. Subjects of the scientific sessions will be surgery of the parathyroids, surgery of the lumbar sympathetics, surgery of the colon exclusive of cancer, and surgical conditions in bilharziasis. For information address Dr. L. Mayer, general secretary, 72 rue de la Loi, Brussels, Belgium.

Personal—Dr. Ernest W. H. Cruickshank, professor of physiology, Dalhousie University Faculty of Medicine, Halifax, N. S., has been appointed to the regius chair of physiology at the University of Aberdeen to succeed the late Dr. John J. R. Macleod.—Drs. John A. Ryle, Cambridge University, and Matthew J. Stewart, professor of pathology, University of Leeds, have been appointed members of the Medical Research Council of Great Britain to succeed Lord Dawson of Penn and Prof. Arthur E. Boycott.

Dr. Birkhaug Returns to Norway—Dr. Konrad E. Birkhaug, who was for several years associate professor of bacteriology at the University of Rochester School of Medicine and Dentistry, Rochester, N. Y., has been appointed to the chair of experimental medicine at Christran Michelsens Institutt, Bergen, Norway, a position created for him. Dr. Birkhaug is a native of Bergen. He received his medical education partly in Europe and graduated from Johns Hopkins University School of Medicine, Baltimore, in 1924. He went to Rochester in 1925 remaining until 1932, when he joined the Pasteur Institute in Paris as an investigator. At Bergen he will work on experimental tuberculosis and leprosy. While in Rochester Dr. Birkhaug was honored with a civic award in recognition of his work on erysipelas.

LONDON

(From Our Regular Correspondent)

Oct 19, 1935

"A Nation of Medicine Drinkers"

Sir Kingsley Wood, the minister of health, attended a meeting of the London Insurance Committee (a committee of physicians, which administers the panel system). He made a comparison between the conditions of today and those of 1917-1918, when he himself was chairman of the committee. They showed a tremendous increase not only in the numbers entitled to medical benefit but in the number of physicians. The latter had increased from 1,300 to 2,174, and it was satisfactory to note that the payments had gone up from \$2,330,000 to \$3,500,000. But the figures which took his eye were those indicating a rise in the number and cost of the prescriptions in London. The prescriptions dispensed in the year he was chairman totaled 4,377,000, last year they numbered 8,482,000. This was partly accounted for by the increase in the number of the insured persons and the fact that new and expensive medicines had been introduced. But we in England were apparently becoming "a nation of confirmed medicine drinkers," and he doubted whether that was to our good. In England many patients had come to regard a visit to the doctor as synonymous with the receipt of medicine. Scotland, however, had no such love for bottles of medicine. The result was that the cost of medicine under the panel in England exceeded that in Scotland by 58 per cent. There were no known facts connected with the incidence of disease to account for that wide difference. He did not think that the standard of treatment in Scotland was lower or the results of treatment less satisfactory. A considerable portion of the outlay on drugs could be eliminated with advantage to the proper treatment of the people. Sir Kingsley did not go to the root of the matter, which is that the English working class has a profound belief in bottles of medicine and likes to take it. Under the panel system it is to be had without payment, and physicians do not care to endanger their popularity by refusing to prescribe. Of course the placebo has always existed in medical practice and sometimes is unavoidable, but, when it is to be had only for the trouble of visiting or sending to the panel physician, the result is obvious. As reported previously in *THE JOURNAL*, a small payment for each bottle of medicine has been suggested as a check, and this has actually been adopted in Canada.

The Right to Die

Euthanasia is a constantly recurring subject of discussion both in the profession and among the people. Various proposals have been made to give the physician the legal power to terminate suffering in incurable disease, and of course objections have been made on religious or other grounds. At last a society called the Voluntary Euthanasia Legalisation Society has been formed. Its object is summed up in the following words: "Individuals who have attained to years of discretion, and who are suffering from an incurable and fatal disease which usually entails a slow and painful death should be allowed by law, if they so desire and if they have complied with requisite conditions, to substitute for the slow and painful death a quick and painless one." The society has received influential support from physicians, lawyers, churchmen, politicians and others. Lord Moynihan is the president, and the executive committee includes Sir Humphry Rolleston, formerly president of the Royal College of Physicians, Sir Walter Langdon Brown, emeritus professor of physic, Cambridge University, Sir James Purves-Stewart, neurologist, Sir Leonard Hill, physiologist, Sir Pendrill Varrier-Jones, founder and director of the Papworth Village Settlement for Tuberculosis, Sir George Seaton

Buchanan, vice president, League of Nations Health Committee, Sir W. Arbuthnot Lane, Prof. Julian Huxley, biologist and author, Prof. H. J. Laski, professor of political science, London University, Rev. Prof. J. M. Creed, professor of divinity, Cambridge University, and the earl of Listowel, a writer whose books include "The Values of Life." To meet possible objections on religious grounds, a statement that what is proposed is not contrary to Christian principles has been signed by well known churchmen such as Dean Inge, Dr. Matthews, dean of St. Pauls, Canon H. R. L. Sheppard, and Dr. T. Rhondda Williams, chairman of the Congregational Union. An inaugural public meeting of the society will be held in London in December. Any one can become a member for the single minimum payment of \$1. A lawyer has superintended the drafting of a bill entitled "The Voluntary Euthanasia Bill," which will be brought forward by Lord Moynihan in the house of lords. It is hoped to arouse public support for the bill to enable persons in great pain and with no hope of recovery to be relieved with their own consent. There is no question of enabling a person to be put out of pain against his will. The public will be safeguarded by the necessity of obtaining the signatures of two physicians. The idea has been in the minds of many people for a long time. The bill and the formation of the society are the result of four years of untiring work by Dr. C. Killick Millard, until recently health officer for Leicester. The wording of the application form as proposed in the bill is as follows: "I am _____ years of age and am suffering from a disease involving severe pain, which, as I am informed, is of an incurable and fatal character. I have consulted my nearest relatives and have to the best of my ability set my affairs in order. I have requested _____, a medical practitioner holding a license under the act, to administer euthanasia if permission is granted and he has consented to act. I am desirous of anticipating death by euthanasia and hereby make application for permission to receive euthanasia." If the referee, after seeing the applicant, gives his permission, the applicant would be given seven days to change his mind.

In a press interview Lord Moynihan said that he did not think there was a physician of long experience in this country who had not had requests for death made to him by patients. "Many people," he added, "insist that 'God sent suffering into the world.' But they seem to forget that God also sent the means of relief. Our duty at present seems to be to keep people alive, even when their lives are useless, at the expense of great suffering. Some of us in the medical profession are unhappy when this necessity is inflicted upon us. We feel that under the strictest supervision power should be given to end life that is a curse to itself and a torture to all who love the afflicted individual. There is nothing compulsory about our proposals. The patient would decide for himself or herself whether the right to die should be exercised." Asked if he himself would submit to euthanasia if he were suffering from a painful incurable complaint, Lord Moynihan said, "I do not know any body who would not."

THE RIGHT TO KILL

English law recognizes no right to kill except in cases of self defense. The termination of hopeless suffering gave rise to a trial for murder a few days before the formation of the Voluntary Euthanasia Legislation Society was announced. There was the difference that death was not voluntary on the part of the patient. At the central criminal court a woman, aged 22, was tried for matricide. Her mother was in a hospital suffering from dementia paralytica. Evidence was given that she was devoted to her mother and that her great interest in life was the hope of her recovery. Her visits to the hospital so distressed her that friends tried to prevent her from going. Finally she got hold of a prescription for soluble barbital and by going to various pharmacists obtained 160 grains (10 Gm). She stated

that she put the barbitol in four peppermint creams and gave it to her mother "as an act of pity." The mother died and Dr Roche Lynch, government analyst, gave evidence that death was due to bronchopneumonia and that a fatal dose of barbitol had been administered. He did not think that the sweets could have contained as much as 160 grains, having regard to their size, but 50 grains (3.25 Gm) was an average fatal dose. The judge pointed out to the jury the danger of accepting the defendant's plea, "I killed in pity." Sympathy had no place in the finding of a verdict, but if they returned a verdict of "guilty" they might make what recommendation for mercy they desired. They should do their duty with firmness and resolution. The case was of great public importance. If the defendant caused death, she did so for a reason which could not be justified in this or any other country. Whether the disease from which her mother was suffering was incurable or not was not a question for them or for him. If life was shortened only by a day, that constituted murder. However, the jury returned a verdict of "Not guilty" and the prisoner was discharged. There does not appear to be any other case in which such a plea was accepted, and the verdict was clearly contrary to the law.

Facilities for Physical Training

Representatives of 140 national organizations concerned with recreative physical activity, with other delegates numbering over 300, attended a conference in London organized by the Central Council of Recreative Physical Training. Lord Astor, who presided, said that at present only 10 per cent of the juvenile population had facilities after they left school for regular exercise. Many young persons deteriorated physically when they no longer had organized exercise or the discipline of school, and the enforced idleness endured by some sapped their mental and physical alertness. Capt S J Parker, government staff inspector of physical training, said that the conference marked the beginning of an effort long overdue to provide means whereby the benefits of physical training and recreative activity might be made readily available to those of post-school age. The work of national voluntary associations was of inestimable value as a foundation, but correlation of their activities was necessary. It then remained to provide for those not associated with any organized body. There was a widespread demand among people living in unfavorable social conditions for help to get things going. They must consider what could be done to ensure the continuity of rational physical training from the school onward. The board of education was about to issue for the guidance of voluntary bodies and local authorities two books on recreation and physical fitness, one for youths and men and another for girls and women. Another publication would give advice with regard to gymnasiums and equipment. An adequate supply of trained leaders was a necessary preliminary to progress. The central council proposed to organize a summer vacation course for 500 leaders at the Carnegie Physical Training College. One member suggested the establishment of a national physical training college and stated that he happened to have a site which he thought would be ideal for the purpose. He would be glad to hand over to the council as much land as it desired for the erection of the college. It was announced that this offer would be considered by the executive committee.

Social Progress and the Unfit

In an address to the York Medical Society Lord Dawson, president of the Royal College of Physicians, said that as society had developed natural selection had lessened. Today the progress of medical science, the qualities of justice and mercy, and the organized efforts of the community were bringing it to naught. And so the "unfit" were preserved. Nature's method of securing quality of population involved a high death rate as well as a high birth rate. In this way there was a wide though rough selection. If nature's method of a high death rate was displaced,

quality of population must be secured in another way. Much was heard of economic 'planning' in order to secure greater welfare for the people. What would this avail unless a like attention was given to "planning" for a healthy race?

Civilization having in large measure nullified nature's methods of eliminating the unfit, needed to replace these methods by control of environment and inheritance. This could be done by methods of nurture to build up fit citizens, having regard to their biologic capacities, and by preventing damage to the community by the 'unfit' producing bad stock and bad homes. A missionary campaign throughout the land to teach housewives the values of essential foodstuffs and how to cook was desirable. The right nourishment of the young body was so important that the assumption by the state of an adjunctive responsibility for the feeding of children became justified. Physical education should be a prominent, if not the first, item in the school curriculum.

Turning to prevention, Lord Dawson said that sterilization should be done in the interests of the race. It was a branch of therapy comparable to inoculation. But there were no means by which carriers of defects that would appear when mating took place with a similar carrier could be detected, though it was not unreasonable to hope that such might be discovered. On the other hand, persons with mental defects were a demonstrable danger, and those with the milder forms were able to live in the community. Sterilization was a restraint of freedom to procreate, but the law already restrained liberty in matters of communal health. Why, therefore, should not future generations be protected? The practice of sterilization was not new, rather, this country had lagged behind. It had been in force in Switzerland for nearly fifty years, and in California and certain other states for a long period. It was now recognized in Denmark, Sweden, Norway, Finland and Germany as a means of preventing hereditary physical and mental defects from damaging the stock.

British Ambulance for Abyssinia

The British Ambulance for Abyssinia has been officially recognized by the British and Ethiopian governments. Advance officers dispatched from this country have reached their destinations and are making arrangements for the entry of personnel and transport into Ethiopia through French or British Somaliland. In the neighboring British colonies of Kenya and Uganda, trained native medical personnel is being recruited with the cooperation of the governor. It is already stated that forty native dressers and three Indian subassistant surgeons are available. Arrangements are being made in London, as far as the funds allow, to dispatch medical officers. Young unmarried men with some surgical experience are preferred. An appeal for funds has been made to the British public and the response has been remarkable in the large number of small subscriptions received, showing the sympathy of persons who are not in affluent circumstances. When complete, the unit will consist of one field hospital and one casualty clearing station with seven medical officers, two administrative officers, transport officers, trained dressers and equipment. The sum of \$175,000 is required for sending out this ambulance and maintaining it in the field. An urgent message has been received in London from the emperor of Ethiopia stating that the northern army is without medical aid and urging that an ambulance unit should be sent. The address of the British Ambulance Service in Ethiopia is 33 Alfred Place London, S W 7. At the same time the Save the Children Fund is organizing relief for Abyssinian refugees in the neighboring British colonies of Somaliland and Kenya. The London missionary societies are making arrangements for their missionaries of whom some are physicians and others have had some medical training, to do ambulance and hospital work. There are also American missionaries taking up this work.

PARIS

(From Our Regular Correspondent)

Oct 11, 1935

Forty-Fourth Annual Surgical Congress

The French Surgical Association held its annual congress at Paris during the week of October 7. The subjects chosen last year to be discussed at the present meeting were (1) infarct of the mesentery, (2) fractures of the os calcis and (3) technic and physiologic sequelae of operations on the diaphragm. As is customary in the larger French societies, two members are appointed at the preceding annual meeting to prepare a complete survey of a given subject and to read this report in abstract form at the following annual congress. A copy of such a report in monograph form is sent to each fellow of a society a month before the meeting, so that a complete discussion can take place as soon as the abstract has been read at the congress.

Drs. Ameline of Paris and Lefebvre of Toulouse submitted an exhaustive review on "Infarct of the Mesentery." Although it was originally considered as always due to a mechanical obstruction of the mesenteric vessels, more recent clinical and experimental observations have shown that other causes play an important part in the etiology, hence the best definition of the infarct is an "ensemble of circulatory disturbances, ending in the escape of blood into the tissues of the mesentery and of the corresponding portion of the intestine."

(a) Pathologic Anatomy. Recent studies, especially those of Hovelacque, show that a free anastomosis exists between the mesenteric vessels. It is impossible to distinguish, on naked-eye or microscopic examination, an infarct of arterial from one of venous origin. Of special interest are the cases of infarct without apparent vascular lesions and also those of infarct that recover spontaneously. The infarct is always limited to a certain segment and is accompanied by a serosanguineous peritoneal exudate and a hemorrhagic exudate into the wall of the involved small intestine.

(b) Etiology. A hard and fast line can no longer be drawn between venous and arterial lesions, because they are constantly associated, from both the anatomic and the pathologic standpoints, even without intervening involvement of the capillaries. Infarction can occur at any age and not, as was formerly believed, only in elderly persons. About two thirds of the reported cases have been in males. Among local causes, appendicitis, salpingitis, enteritis and gastroduodenal ulcers deserve mention. Among general causes, cardiovascular disease, blood dyscrasias such as purpura and hemophilia, infections, diabetes and operations on the gastro intestinal tract are to be considered. In seventy-one of 490 cases there was a history of such an operation within a reasonable period before the infarct. In ninety-seven cases, referred to for the present as cryptogenic, no local or general cause could be found.

(c) Clinical Aspects. Infarct of the mesentery as a rule presents the clinical picture of an acute onset, with a pain of variable intensity, most often referred to the right iliac or umbilical or epigastric region and accompanied by vomiting of a bilious or bloody (10 per cent of the cases) character. Although signs of intestinal paresis are most frequently observed, a serous diarrhea may occur. Bloody stools were formerly believed to be pathognomonic of infarct, but this symptom was observed in only one fifth of the cases. The abdominal examination is of little aid, because rigidity is generally absent and there may be only slight tenderness, which increases as one approaches the involved segment. On percussion, according to Mondor and Ameline, there is well marked dullness over the infarcted segment.

Shock appears early. None of these clinical signs are pathognomonic for infarct. Examination of the blood reveals a rapidly increasing leukocytosis. Roentgenographic study has thus far not been of any aid.

The acute conditions that are most frequently mistaken for infarct are ileus, peritonitis and acute appendicitis. The clinical signs of these are not so different in type from infarct but they differ sufficiently to enable a preoperative diagnosis of infarct to be made. In ileus the abdominal distention is more marked, there is little pain or shock and vomiting occurs later.

In diffuse peritonitis the abdominal distention is more generalized, the vomiting is more of the projectile type and the pain is not localized. In acute appendicitis the abdominal rigidity and tenderness are in the right iliac region, the pain is less intense and there is no shock.

The prognosis of mesenteric infarct has not improved much recently. There were 331 deaths (operative and nonoperative), or 73.55 per cent, among 450 collected cases, and 120 cures, or 26.45 per cent. The most unfavorable cases are those of cardiovascular origin, the mortality rate being 90.67 per cent. The more favorable cases are those in which there has been no previous illness. In these the mortality was 62.2 per cent. The authors were able to collect twenty-one cases in which spontaneous recovery occurred.

(d) Pathogenesis and Mechanism. Simultaneous arterial and venous obstruction is most common, but infarct may occur without a vascular lesion. The role of the nervous system in the form of vascular spasm is certainly more important than has heretofore been considered to be the case. The same is true of infection and of anaphylactic or toxic shock.

(e) Treatment. Of the 450 collected cases, operation was performed in 332. After simple exploration there were eighty-seven deaths and twenty-one recoveries. After resection, short circuiting, and so on, there were 131 deaths and ninety-three cures. Resection hence offers the best chances of success.

In the discussion, Havlicek of Czechoslovakia called attention to his work showing direct anastomosis between arteries and veins without intervening capillaries. This has been confirmed by others for various viscera.

Leriche of Strasbourg believed that the anatomic and not the physiologic factor had been considered too long. The intestinal circulation possesses a vasomotor regulatory mechanism, as does that of the vessels of the extremities.

Arterial pathology is primarily a functional disturbance, and mesenteric infarct is due to the same mechanism as vascular troubles in general. The infarct is the result of the anemia, the hemorrhagic infiltration being secondary. For this reason the process may cease in the "spasm" stage and recovery may result.

Important Notice on BCG Vaccination

The commission appointed by the Pasteur Institute to investigate the efficacy and also to receive reports of the failures of the BCG vaccination method against tuberculosis in infants has issued a statement to the effect that animal experiments and clinical observation show that the immunity conferred by the BCG (Calmette-Guerin vaccine) is established only after a certain length of time, often only after a long interval, and that during this period the infant is susceptible and can be infected as if it had not been vaccinated. Hence it is essential to avoid all contacts with tuberculous individuals during this period. Such isolation is as necessary for vaccinated as for nonvaccinated infants.

Opposition to Social Insurance Orders

A recent order by social insurance authorities, to the effect that records of insured workers while under treatment in private hospitals must be accessible to medical inspectors for the social insurance organizations, is arousing both criticism and protests. The Société de chirurgie passed a resolution at the June 20 meeting to the effect that such a rule is contrary to the duty of a physician or surgeon as to professional secrecy, and placed itself on record as opposed to any ruling that would allow such records to be open to inspection by representatives of the social insurance authorities.

Rigorous Requirements for Obtaining the Title of Doctor

For many years attention has been called, both at home and abroad, to the fact that the bestowal of the title of doctor by German universities is not in keeping with the dignity that the title is supposed to convey. Particularly during the period immediately following the World War, things went so far that every one who planned to play any prominent part in society or in industrial life felt obliged to secure some sort of doctor's title. It has been rumored that at many universities, particularly at the smaller provincial institutions, there has been a tendency to "let down the bars," and even the comic journals have made the new "doctors" the butt of their jokes. It is alleged also that the honorary title *doctor honoris causa* has often been attained in the simplest manner—sometimes as evidence of appreciation of a considerable gift of money. Respect for the doctor's degree has consequently been lowered in the public mind, in spite of many attempts on the part of the more discerning members of academic circles to check the growing lack of confidence. Some sixty years ago Theodor Mommsen, historian of the University of Berlin, published his article on "The German Pseudo Doctors" which aroused a great furor. The publication of this revealing article led to the adoption of the regulation that a certain number of copies of a doctor's thesis must be printed and circulated which furnished an effective means of public control of the various faculties of the universities. At that time the examinations for the doctor's degree constituted also a considerable source of income. The pecuniary feature of the problem was later partly solved by issuance of the decree that the examination fees should not be credited in full to the examiners but should go chiefly into library, university and faculty funds. What did not go into these funds was to be divided among the four examiners who held the oral examinations and the two persons selected to discuss the contents of the thesis presented by the candidate for the doctor's degree.

Now the minister of public instruction (Rust) has made several sharp changes in the regulations. The graduation fees incident to the obtaining of the doctor's degree at any German university have been placed uniformly at 200 marks (\$80, current), which sum is payable in full into the government treasury, the professors receiving no part of it. University instructors will henceforth perform the work of examiners as part of their regular duties. The reasons assigned for this decree are significant. The bestowal of the title of doctor is one of the most exalted rights of the faculties of the German universities. The exercise of this right is associated however, with certain high obligations.

Under all circumstances, therefore, the university authorities must see to it that only such students or scholars are admitted to the examination for the doctor's degree as have shown that they are competent to state a problem correctly to grasp its significance and to elaborate on it in accordance with scientific methods. The doctor's degree must never be bestowed for superficial reasons as a complement of a successfully passed government (or similar) examination on the basis of a more or less formal performance. Through the granting of degrees on a flimsy basis the German doctor's degree has already lost much of its former prestige. The decree stipulates also that candidates for the doctor's degree must be the actual pupils and scientific collaborators of the instructor and that between pupil and instructor a spirit of camaraderie must exist. Only under these points of view shall candidates for the doctor's degree be accepted and aided and the rectors or presidents of the universities shall see that these requirements are observed.

This decree is intended to have a salutary effect on the conferring of the title of doctor of medicine. In the past it has often been granted in a routine way on the basis of a report on some clinical case or other which had no scientific value. The number of applicants for the doctor's title was greatly influenced by the actual or supposed advantages accruing therefrom to the possessor, that is, by the esteem in which it was held in the public mind. Through the operation of this decree the German doctor's degree will gain in prestige, although it may take some time for it to recover its former status.

Distribution of Medical Students in Germany

The matriculation of medical students at German universities for the summer semester 1934 (which included 890 foreigners) numbered 23,028. The largest proportion of these students are derived from the families of middle rank officials (5,892) and merchants and industrialists (4,547). Only 2,391, or 10.8 per cent, are the sons of physicians, while about 30 per cent of the fathers of these students had a complete university training. It is evident, therefore, that our future physicians are recruited mainly from nonmedical circles. Slightly more than 1,000 students are from the families of agriculturists—chiefly from those of middle rank. Children of laborers have a comparatively high representation (315), being greater, for example, than the children of pharmacists (214). About 25 per cent of the women medical students are the daughters of higher officials and a further 25 per cent are from the families of middle rank officials. The University of Munich has the highest representation of medical students (2,528), the University of Berlin comes next with 2,273 students. Next in descending order come the universities of Würzburg, Königsberg, Bonn and Heidelberg. The University of Gießen has the smallest representation. Of the 890 foreign students (120 women), 517 are from Europe, most of them from Poland, Rumania, Danzig and Switzerland. There are only nine students from England and only one from France. From Asia there are seventy-one, forty-two being from China. Africa has furnished thirteen and North America 207, 206 being from the United States. From South America come forty-six, twenty-four from Peru. From the religious point of view 327 foreigners were of the Protestant faith, 209 were Catholics and 173 were Jewish.

Criteria for Correct Nutrition

For some time the health authorities have given increased attention to the problems of nutrition. Another evidence of increased interest in nutritional problems is the fact that on August 1 a 'department of physiologic nutrition' was established within the federal bureau of health, of which Professor Floessner was appointed director. Furthermore the creation of a special official commission to deal with purely scientific nutritional problems is contemplated. The Reichsarbeitsgemeinschaft für Volksernährung which recently established a set of criteria for correct nutrition, to be used in connection with the educational campaign, is working along the same line. The criteria state that an effective nutrition can be accomplished by means of a wide variety of diets and with the aid of widely different food articles. A one-sided diet is condemned, irrespective as to whether it is a meat diet or a vegetarian or raw-food diet. The most important prerequisites of any diet are full food value and price-worthiness.

The basis of the educational and the publicity campaign for better nutrition lies in the paramount emphasis that is placed on a mixed or well assorted diet which should comprise adequate amounts of fruits, green vegetables, and milk and milk products. Purely vegetarian nutrition is not advocated. If certain persons for some special reason wish to adopt a vegetarian diet, no objections need be made. However an abrupt transition from a mixed diet to an exclusively vegetarian diet should not be undertaken without consultation with a physician. Raw food

is valuable as supplementary nutrition, in the form of salads, fruit and the like, but an exclusive diet of raw foods should not be adopted by any one without a physician's endorsement. Diets influenced by cultist trends the *reichsarbeitsgemeinschaft* refuses to approve. As to what constitutes a suitable diet for various types of patients must not be made the subject of public lectures or of educational or publicity campaigns.

AUSTRALIA

Annual Meeting of British Medical Association at Melbourne

In recognition of the development of medicine in Australia, the one hundred and third annual meeting of the British Medical Association opened in Melbourne September 9 and continued for that week. On only three occasions has the annual meeting been held outside Great Britain, and Canada had been chosen for the previous two.

It became apparent at this meeting that Australian medicine possesses a tradition and a character of its own. In a country where many local delegates travel 2,000 miles in a straight line to the meeting but which contains a mere seven million people there are problems of medical care that are unique in the world. The juxtaposition of the temperate and tropical zones provides a range of pathologic possibilities and physiologic permutations that gives a lively variety to Australian medicine.

For the first time in the history of the association an Australian born was chosen as the president. In thus honoring Sir James Barrett, K.B.E., CB, CMG, LL.D., M.S., F.R.C.S., a distinguished ophthalmic surgeon and medicosocial organizer, the association also honored the illustrious sons of Australia, who in their native country and overseas have achieved eminence in most branches of their profession.

The meeting was also honored by the presence of medical scientists from Great Britain, who passed through the United States on the way. Incidentally, the British delegates expressed gratification at their kind reception during their crossing of America, their most intriguing experience being their tour of Chicago with the police patrol.

ANNUAL GENERAL MEETING

Adjourned July 23 from London across the world to Melbourne September 10, the annual general meeting opened the proceedings in the Town Hall in an atmosphere of austere procedure and colorful pageantry. One of the first acts of the newly elected president was to send, with the approval of the meeting, a cablegram to King George, the patron of the association, expressing loyalty and devotion. Before the conclusion of the meeting, a suitable reply was received. The governor general of Australia welcomed the members who had come from other parts of the empire and said that the importance of mankind which every congress of this nature carries is heightened by the inspiring fact that this notable assembly is an inter-imperial one. The following representatives of other associations were introduced and welcomed to the meeting: Canadian Medical Association, Dr. R. D. Rudolph and Dr. Ritchie, Federal Council of the Medical Association of South Africa, Dr. C. M. Murray, Chinese government and Chinese Medical Association, Dr. Wu Lien-teh, Japanese Medical Association, Dr. Genzo Katoh, Australian Federal Council, Sir Henry Newland. A distinguished foreign guest, Dr. K. Herman Bouman of Amsterdam, and delegates from overseas dominions, colonies, dependencies and mandated territories, were also received officially. An award of the association was presented to a Melbourne scientist, Dr. F. M. Burnet, for his work on bacteriophage and virus diseases.

THE PROBLEMS OF THE HOSPITAL SYSTEM

In his presidential address, Sir James Barrett urged the members to take charge of the future of the hospital system. "If hospitals are nationalized, the whole medical profession will inevitably sooner or later be nationalized," he declared. "The choice must be made, or we may drift by indecision into a position difficult to justify or to alter. The fault of the present hospital system is that the economic gap between the public hospitals and the so called intermediate hospitals and the private hospitals is too great and should be bridged by a contributory system such as bush nursing, in which case the hospital charges for intermediate patients may be made very small. If such a contributory system is adopted by the profession, the profession will exercise its just influence in managing it. If, on the other hand, it is supplied by the state or other organizations and the members of the medical profession do not play an active part in its establishment, then their control and influence will probably be negligible. Now is the time to decide and to choose which system is preferable." In dealing with the main subject, Sir James Barrett discussed four different systems: (1) the Victorian Bush Nursing Association, (2) the hospital system of Victoria, (3) the hospital system of Great Britain and (4) the hospital system of New Zealand.

The bush nursing movement began in 1911 and had developed steadily until in 1925 there were forty four nursing centers and three hospitals. As hospitals were established the contributory scheme that had been applied to the nursing centers was transferred to them. Contributors could obtain unlimited nursing and hospital attention for themselves and their dependents up to a certain age for £2/2/- a week, but all patients had to make their own arrangements with their medical attendant, a system which, being essentially human, had worked exceedingly well. These hospitals receive and request nothing from the government for construction and, except in six instances of special and really historical interest, nothing for maintenance. They must maintain themselves or close. So far none have closed, and at present these hospitals, staffed by doubly and trebly certificated nurses and not by trainees, by nurses who are the best paid nurses in the state, provide the cheapest hospital accommodation in the state. From one third to one sixth of the cost of construction has been borne by the Edward Wilson partnership and the H. V. McKay trust. The remainder has been provided by the districts that own them.

Sir James Barrett explained that the public hospitals in Victoria were maintained by voluntary contributions, by government subsidy and by the contributions of patients. There were also intermediate hospitals, mostly organized by religious bodies, at which the charges, although in his opinion too high, were less than those of the private hospitals. In pointing out the difficulties of financing the present system, he said that 85 per cent of the taxpayers in Victoria received £300 a year or less. Many of that percentage would have to receive necessary hospital and nursing attention at rates within their means. The sole cause of the hospital problem was that thousands of people now resorted to the public hospitals who did not before. A great change of attitude has taken place and we shall have to alter our ideas and outlook and meet the difficulties arising from it. "Are we to abandon our voluntary charitable system and nationalize—that soothing word!—our hospital service?" asked Sir James Barrett. "If so, we shall lose the humane feelings of the public and of the profession which brought the hospitals into existence and which have ensured their continuance. The medical staff must then cease to be honorary. Unless the experience of other countries misleads us, the cost will be great if efficiency is to be maintained. One essential factor has not been faced. It is quietly assumed that the medical expert will continue to act as if the system were a charitable one, so far as he is concerned. If nationalized hospitals make their appearance, the medical officers must be adequately paid if efficiency

is desired. Intermediate hospitals are not cheap enough. Why should the contributory bush nursing principle not be applied, and the cost to the patients be substantially reduced? Why should there not be hospitals of the bush nursing type in the suburbs?"

PUBLIC CONTROL OF HOSPITALS

The author of a surgical textbook of world-wide use, Prof E. W. Hey Groves, professor of surgery at the Belfast University, delivered the first Hamilton Russell memorial lecture at the Royal Australasian College of Surgeons. I say with all the emphasis at my command that the time has come when every hospital which undertakes the treatment of the sick and the investigation of disease must come under public control. The multiplication in the number and variety of hospitals was a very real problem. In the old days the only reason and justification for hospitals was the charitable desire that poor people should be housed, fed, nursed and doctored during illness. No person who had a house and servants and who could be attended at home would have thought of going to a hospital. Actually hospitals in those prehistoric days were hotbeds of disease and infection. "But since surgery has become a science and since all manner of investigations are necessary for the diagnosis and treatment of disease, the hospital has become the essential place where all surgical work must be done," continued the lecturer. "It is no longer a question of the man of means being treated at home while the poor man is sent to an institution. Unfortunately, this changed relationship of hospitals to the community has come about so slowly that it is not realized and there are many even today who do not appreciate its significance. Therefore, we have the present muddle of various types of institutions, provided for the sick, without clear definition of the scope of each or the proper relationship to one another."

"First, there are the voluntary hospitals. In our country it is usual and right to express admiration and gratitude for these voluntary hospitals, which have been the scene of nearly all the advances of discovery and technique. But however sincere may be our admiration for their work in the past, we are bound to criticize their present position and their relationship to the public health service. The voluntary hospital is essentially an institution founded and, to some extent, endowed and wholly managed by private individuals. At one time they were supported entirely by voluntary subscriptions, and the patients were treated free of charge. Now this is all changed. A large proportion of their maintenance charge has to be borne by fees paid by the patients, but in spite of this and they are all finding it hard to live, while extensions and improvements have to be delayed until some wealthy benefactor can be found to present them with the needed money. To me this has always seemed wrong in principle and bad in practice, and I have always protested against the indignity of medicine being a mendicant. But the essential fault in the voluntary hospital system is the much vaunted independence of control of the voluntary hospitals. The time has come when every hospital which undertakes the treatment of the sick and the investigation of disease must come under public control, for example, that of the Ministry of Health. It should be no longer possible for a private person to give or bequeath a hospital to the community without inquiry by the Ministry of Health as to how that hospital is to be supported whether it is needed and above all how it is to be staffed. Now that the hospital represents a scientific clinical laboratory in which the work must be highly differentiated and specialized, it is obvious that multiple small hospitals with no connection with one another and no responsibility except to their own directors, are an absurdity. Uncontrolled independence of voluntary hospitals presents one of the most urgent problems of today. Either the voluntary hospitals must set their own house in order and set up a council of government which shall be concerned only for the good of the community and of scientific progress or else the state must control them."

Maintenance must be met by insurance instead of mendicancy, and new hospitals and new buildings must be provided by the public funds."

Professor Hey Groves referred briefly to municipal hospitals in Britain and to nursing homes, of which he said "Let us hope that the force of circumstances will speed up the disappearance of the proprietary nursing home, which is surely an anachronism today. In the future all the best hospitals should have ample accommodation for private patients who can pay their own fees and maintenance and at the same time obtain the benefit of all the refinements of scientific medicine and surgery."

In the early part of his lecture, which was entitled "The Romance of Surgery," Professor Hey Groves gave an outline of the life and work of Hamilton Russell, who died in Melbourne in 1933. The professor said that Hamilton Russell's innate modesty forbade him to take pride in anything but the fact that he was the pupil and last house surgeon of Lister, whom he ever delighted to honor and to imitate. Professor Hey Groves discussed Russell's sacral theory of herma, his simple and effective method of treating fractured femurs (known now as the Melbourne method), and his contribution to the surgical technique of treating strictures.

SKIN DISEASES IN AUSTRALIA

Dr Herman Lawrence of Melbourne stated that the Australian people were more subject to skin diseases than any other people in the world. This was due to the dry atmosphere and the outdoor life of the people. A suggested investigation was the relationship of mice plagues to skin disease.

THE FLYING DOCTORS

Relating the history of the services, Dr Vickers paid a tribute to Rev John Flynn, superintendent of the Australian Inland Mission of the Presbyterian church, to whose inspiration and tenacity of purpose they owed these services today. Prior to 1914 he realized the need for medical facilities for the lonely settlers in remote parts and conceived the idea of having a doctor at a central base, with an airplane to visit and, if necessary, transport patients to hospitals. Wireless was essential as a means of communication, and in 1926 a complete transmitting and receiving set was evolved. The power of this type of set was derived from a small high tension generator driven by bicycle gears, which ensured an unfailing supply of electricity and made the set capable of being operated by anybody. For distances up to 200 miles vocal messages could be sent and received. Outside that radius Morse code was transmitted from a simple typewriter keyboard, which made actual knowledge of Morse unnecessary. There were at present thirty-five of these sets at station homesteads, mission hospitals and police stations, but the objective was to increase that number to 500 as finances permitted. When vocal messages were received the doctor was often able to give simple instructions, particularly in the case of minor ailments of children to worried mothers 200 miles away from medical aid. In urgent cases, such as severe injury or internal operations, the combination of wireless and airplane meant a saving in many cases of days, and patients transported by air were remarkably free from surgical shock inseparable from practically every other form of transport.

The loneliness of Australia's frontiers was unique. Of Australian cities with a population of more than 10,000, all, with few exceptions, were on or near the coast. In difficult medical cases it was necessary to reach a city of 10,000 or more people to guarantee reasonably adequate hospital facilities. The loneliness was likely to continue for some time, as apart from the transcontinental and mining lines no attempt was being made to build railways into the tropical belt. It was desirable not only to convey patients to the hospital by aerial ambulance

but to bring them back when discharged. A patient brought to a hospital in four hours might have to travel over rough country for three weeks to get home.

AUSTRALIA'S FUTURE

"Our moonlight civilization in Australia mirrors most alarmingly the decline in birth rate and population seen in western Europe, for these things act here, not as a safeguard, but toward disaster" declared Sir Raphael Cilento of Queensland at the combined sessions of public medicine and medical sociology. We cannot preserve our frontiers unless we can effectively occupy the land we claim, and the problem is vast. Certainly we have done well in actual figures. During the period 1911-1921 our annual increase corresponded to 2.01 per cent and from 1921 to 1933, in spite of actual loss owing to the depression, it was 1.83 per cent, the chief increase going to Queensland. But, with regard to distribution, Australia is becoming more urbanized without provision in the secondary field. The percentage of population in country districts fell from 37.35 in 1921 to 35.92 in 1933, and this is the tendency of several decades. "It is in respect of natural increase that our figures are most disturbing. From 1861 to 1931, 75.92 per cent of the population was provided by natural increase and 24.08 per cent by immigration. But during the thirty-two years of recorded figures since 1900 this figure has fallen to 19.23 per cent, and from 1927 the figures for the individual years show a decline that resulted in an actual loss in 1930, 1931 and 1932. (Incidentally, the nominated and selected immigrants fell in number from 30,123 in 1927 to 275 in 1931 and 175 in 1932.)

"The Australian birth rate is now one of the lowest in the world, but fortunately the death rate is phenomenally small, so that a reasonably good showing is made in respect of natural increase, but, as Dublin recently pointed out, the natural increase rate is fallacious. In his experience an American rate of 10.99 per thousand when corrected in terms of the biologic constitution (age frequency of material pregnancy and mortality) becomes no more than 5.47 per thousand. This criterion applied to Australian figures by Exley shows several tendencies that are unfavorable. The average age of the population is rising rapidly, and the proportion of youth is declining. The Year Book of 1933 shows that young and middle aged arrivals have fallen from two thirds to little more than one half, the proportion of older people among them has risen from one in seven to one in three, and, in respect of departures from Australia, the depression prompted many people in the age group 15 to 35 to leave Australia for other lands in search of employment. The best of all immigrants, the baby, formerly represented by 3.34 (1911) per family, has fallen to 2.95 (1932), so that the average issue of mothers has fallen 13.22 per cent and there are considerably fewer potential mothers. The natural increase for 1931 was half that of 1891. Exley concluded from his study that, in terms of natural increase, the stable population of Australia, on present figures, would represent no more than 8,500,000 and would contain an excess of females of approximately 35 per thousand. The solution is immigration or ultimate invasion. Australia depends today for her defense and her development on peace and security, for which there is no guaranty. Health—that is, protection against external disease and a vigorous vitality from right living that is internal excellence—and the dominant mentality that goes with abounding health are both essential to ensure our survival in the period of increasing pressure in the Pacific that appears imminent and inevitable."

THE DOCTOR AS EUGENIST

In clear and candid language the principles of eugenics and the aims of the Eugenics Society of Great Britain were explained by Lord Horder, president of the society. Lord Horder said that those who urged the claims of eugenics found themselves for the most part crying in the wilderness, but they

believed that the gospel which they preached would usher in an epic in the physical and intellectual progress of the human race which would have comparably good results. Eugenics had been defined as "the study of agencies under social control that might improve or impair the racial qualities of the future generations, either physically or mentally." The eugenicist did not believe that permanent results would accrue from pampering the individual. To do one's utmost to start every new life on a sound and sturdy basis was the greatest service one human being could render to another. In medicine there had been a tendency to get back further and further in outlook and in practice. From the cure of the individual patient, medical men had turned to the control of the disease and the increase of the patient's resistance to infection. They called this preventive medicine. They had attended more to the child and less to the adult, and from the child they had passed to the infant and even to prenatal life. But they must go back further still, for, by the time a new individual was conceived, heredity had already stamped on it the power to live healthily or had loaded it with handicaps from which it might never be able to shake itself free. Eugenics in actual fact was the soundest and by far the most profitable form of preventive medicine. Lord Horder suggested that civilization had advanced far enough to enable them to achieve biologic control just as completely as they had achieved physical control. He meant biologic control in the human sphere, since no one seemed to question either the wisdom or the morality of achieving biologic control in the animal and in the plant world. People accepted the principle in relation to horses, cattle and plants but gasped at the idea of accepting the principle in respect of men and women. The principle offended the religious emotions and ideas of some. He did not propose to enter into that arena, for the degree to which a man's religion determined his views on questions of this kind must be settled in the sanctity of his own heart. Supposing the main principle of eugenics to be accepted, the speaker proceeded what should be done to act on it? In the first place, the study of eugenics should be encouraged in the universities and schools, and by the institution of scholarships and research studentships. Eugenics should be taught to medical students. Then the compilation of family pedigrees should be encouraged.

Marriages

- ROBERT D. SCHROCK, Omaha, to Miss Elizabeth Winslow Wetherbee of Newton Highlands, Mass., August 20.
JAMES FRANCIS WILKINSON, Oconomowoc, Wis., to Miss Patricia Phelan Hebert, at Clintonville, August 28.
ALDEN W. SQUIRES, Ann Arbor, Mich., to Miss Marguerite B. Parker of Newton Highlands, Mass., August 5.
HENRY CLAY HARRILL, Ellenboro, N. C., to Miss Maxine Patricia Stout of Pierre, S. D., August 8.
GEORGE ALFRED HESS, Bridgewater, Va., to Miss Helen May Carter of Trenton, N. J., August 18.
JUNIUS RICHARDSON VANN, Spring Hope, N. C., to Miss Matilda Mayo of Clayton, August 18.
LAWRENCE F. STEFFEN, to Miss Aileen Marie Conlan, both of St. Marys, Kan., August 29.
AVISON GANO, Carrollton, Ill., to Miss Maude E. Gronerell of Muskegon, Mich., August 3.
DONALD F. MARION, Harrisburg, Pa., to Miss Mabel Floyd of Fairmont, N. C., in August.
CLINTON S. M. KOERNER, Chicago, to Miss Rosella Fredendall of Rankin, Ill., August 31.
HARRY LINWOOD LEAVITT, Seattle, to Miss Teresa Drumheller of New York, August 22.
FRANCIS LAMBERT MCGANNON, to Miss Louise Houch, both of Cleveland, in August.
FRANCIS X. GRAFF, Freeport, Ill., to Miss Constance Ford of Gary, Ind., August 24.

Deaths

Alexander Crever Abbott, Philadelphia, University of Maryland School of Medicine, Baltimore, 1884, emeritus professor of hygiene and bacteriology, University of Pennsylvania School of Medicine, formerly lecturer in hygiene, Johns Hopkins University School of Medicine, Baltimore, member of the Society of American Bacteriologists, for many years member of the city board of health, served during the World War author of "The Principles of Bacteriology" and "The Hygiene of Transmissible Diseases," aged 75, died, September 11, at his summer home on Cape Cod, of cerebral hemorrhage.

Richard Clinton Bunting, Memphis, Tenn., University of Maryland School of Medicine, Baltimore, 1899, member of the Tennessee State Medical Association, formerly clinical assistant, associate and associate professor of neurology University of Tennessee College of Medicine, on the staffs of the Methodist, St. Joseph's and Crippled Children's hospitals and the Western State Hospital, aged 58, died, September 30, of carcinoma of the pancreas and hemorrhagic pancreatitis.

Henry Schwarz, St. Louis, St. Louis Medical College, 1879, member of the Missouri State Medical Association, professor emeritus of obstetrics and gynecology, Washington University School of Medicine, fellow of the American College of Surgeons, past president of St. Louis Medical Society, aged 79, consulting obstetrician to St. Louis Maternity Hospital and Barnes Hospital, where he died, October 23, of leukemia.

Edward Wells Brown, Northampton, Mass., College of Physicians and Surgeons, Medical Department of Columbia College, New York, 1894, medical examiner of Hampshire County for many years, on the staff of the Cooley Dickinson Hospital, consulting surgeon to the Veterans Administration Facility and the Northampton State Hospital, aged 64, died, October 25, of coronary thrombosis.

David Walker Houston, Troy, N. Y., McGill University Faculty of Medicine, Montreal, Que., Canada, 1881, fellow of the American College of Surgeons, veteran of the Spanish-American War, at one time police surgeon in Cohoes, N. Y., and member of the board of health consulting surgeon to the Troy and Leonard hospitals, aged 78, died, September 11, of carcinoma of the esophagus.

William Henry Clancy, Cambridge, Mass., University of the City of New York Medical Department, 1886, member of the Massachusetts Medical Society, for thirty-five years physician for the Cambridge schools, physician for the Middlesex County Jail, on the staffs of the Cambridge City Hospital and the Holy Ghost Hospital, aged 70, died, September 21, of chronic myocarditis.

Frederick Laurence Flynn, New York, Cornell University Medical College, New York, 1902, member of the Medical Society of the State of New York, visiting surgeon to the Morrisania City Hospital consulting surgeon to the Fordham Hospital and formerly visiting surgeon to the Lincoln Hospital, aged 57, died, October 17, of diabetes mellitus and coronary heart disease.

Edmund Walters Warren, Palatka, Fla., University of Georgia Medical Department, Augusta, 1902, member, past president and secretary of the Florida Medical Association secretary of the Putnam County Medical Society formerly mayor on the staff of the Mary Lawson Sanatorium, aged 60, died, September 24, in the East Court Hospital, St. Augustine.

William Cohen, Brooklyn, Long Island College Hospital, Brooklyn, 1915, member of the American Academy of Ophthalmology and Oto-Laryngology assistant visiting ophthalmologist at the Gouverneur Hospital and an assistant in the ophthalmological department of the dispensary of the Long Island College Hospital, aged 45, died, September 10.

George H. Westinghouse, Buffalo, University of Buffalo School of Medicine, 1886, member of the Medical Society of the State of New York, formerly registrar of vital statistics city board of health for many years on the staff of the Buffalo Hospital of the Sisters of Charity, aged 74, died, October 8, of coronary thrombosis.

John Breckinridge Catlett, Staunton, Va., University of Virginia Department of Medicine, Charlottesville, 1888, formerly city physician, member of the board of health and county coroner for many years on the staff of the King's Daughters Hospital, aged 69, died, September 24, of malignant disease of the pelvic bones.

Roy Arthur Townsend, Fairgrove, Mich., University of Michigan Department of Medicine and Surgery, Ann Arbor

1910, member of the Michigan State Medical Society, health officer of Fairgrove township, aged 52, died, September 18, in the Unionville (Mich.) Hospital, of nephritis and arteriosclerosis.

William Lewis Conklin, Poughkeepsie, N. Y., University of the City of New York Medical Department, 1885, past president of the Monroe County Medical Society, on the staff of the Bowne Memorial Hospital, 1923-1925, aged 77, died, October 4, of cardiovascular disease and hypertrophy of the prostate.

Edward William Cooney, Appleton, Wis., College of Physicians and Surgeons of Chicago School of Medicine of the University of Illinois, 1904, member of the State Medical Society of Wisconsin, on the staff of St. Elizabeth Hospital, aged 61, died, September 11, of coronary thrombosis.

Silas Green Cain, Somerset, Ky., University of Louisville Medical Department, 1893, member of the Kentucky State Medical Association, served during the World War, on the staff of the Somerset General Hospital, aged 64, was found dead in bed, September 12, of coronary thrombosis.

Lester Blake Cavins, Bloomington, Ill., Baltimore Medical College, 1904, medical director of the State Farm Life Insurance Company, served during the World War, aged 58, on the staff of the Brokaw Hospital, Normal, where he died, September 28, of coronary thrombosis.

Maria Mitchell Vinton, Brightwaters, N. Y., Woman's Medical College of the New York Infirmary for Women and Children, New York, 1886, formerly medical inspector of the New York City Health Department, aged 72, died, September 20, of carcinoma of the stomach.

Allen Tindolph Agnew, International Falls, Minn., University of Minnesota Medical School, Minneapolis, 1917, member of the Minnesota State Medical Association, served during the World War, aged 44, died, September 28, in the Northwestern Hospital, Minneapolis.

John Hamilton Hastie, Stockton, Ala., University of Tennessee Medical Department, Nashville, 1899, member of the Medical Association of the State of Alabama, aged 57, died in September at an infirmary in Mobile of injuries received when his car crashed into a tree.

Charles David O'Hara, Williamstown, Ky., Medical College of Ohio, Cincinnati, 1895, member of the Kentucky State Medical Association, past president of the Grant County Medical Society, aged 61, was found dead in his office, September 18, of cerebral hemorrhage.

Thomas R. Barker, Danville, Ind., Central College of Physicians and Surgeons, Indianapolis, 1901, past president of the Hendricks County Medical Society, for many years on the staff of the Methodist Hospital, Indianapolis, aged 60, died, October 7, of heart disease.

Robert Abbott Donahoe, Lowell, Mass., University of Vermont College of Medicine, Burlington, 1921, member of the Massachusetts Medical Society, aged 43, on the staff of St. John's Hospital, where he died, August 20, of acute hepatitis and cirrhosis of the liver.

Arthur T. Caine, Anoka, Minn., University of Minnesota College of Homeopathic Medicine and Surgery, Minneapolis, 1899, medical superintendent of the Anoka State Asylum, aged 60, died, September 12, in the Littel Hospital, Minneapolis, of cardiac decompensation.

Neil McLeod, Philadelphia, McGill University Faculty of Medicine, Montreal, Que., Canada, 1927, instructor in pathology, University of Pennsylvania School of Medicine, aged 34, was instantly killed, September 23, in an automobile accident near Lakewood, N. J.

Albert Henry Fridenberg, New York, College of Physicians and Surgeons, Medical Department of Columbia College, New York, 1877, at various times on the staffs of the Mount Sinai and Beth Israel hospitals, aged 80, died, October 3, of chronic myocarditis.

Spencer C. Alexander, Salt Lick, Ky., University of Louisville Medical Department, 1890, member of the Kentucky State Medical Association, formerly county coroner, aged 78, died, September 21, in the Good Samaritan Hospital, Lexington, of heart disease.

David James Molumphy, West Hartford, Conn., Jefferson Medical College of Philadelphia, 1906, for many years medical inspector of the city board of health, on the staff of St. Francis Hospital, Hartford, aged 59, died, August 31, of hypernephroma.

John A. Campbell, Nahant, Ga., Medical College of the State of South Carolina, Charleston, 1911, member of the

Medical Association of Georgia, also a druggist, aged 50, died, September 20, in a hospital at Waycross, of gangrenous appendicitis

Julius Crisler ⊕ Jackson, Miss., Jefferson Medical College of Philadelphia, 1898, past president of the Central Medical Society, fellow of the American College of Surgeons, aged 59, on the staff of the Jackson Infirmary, where he died, September 13

Hezekiah Levin Martin, Birmingham, Ala., Vanderbilt University School of Medicine, Nashville, Tenn., 1881, member of the Medical Association of the State of Alabama, Confederate veteran, aged 87, died, September 2, of cardiovascular disease.

John Sullivan Clifford, Rochester, N. Y., George Washington University School of Medicine, Washington, D. C., 1906, for many years on the staff of St. Mary's Hospital, aged 57, died, September 6, of cerebral hemorrhage and arteriosclerosis

Abram Burton Jones, Tyrone, Ga., Atlanta School of Medicine, 1907, member of the Medical Association of Georgia, mayor of Tyrone and member of the board of education, aged 59, died, September 6, of carcinoma of the liver

Benjamin L. Simmons, Nashville, Tenn., Georgia College of Eclectic Medicine and Surgery, Atlanta, 1890, president of the state board of medical examiners, aged 72, died, September 23, of valvular heart disease and hemiplegia

George Zina Goodell, Salem, Mass., Harvard University Medical School, Boston, 1881, member of the Massachusetts Medical Society, formerly on the staff and superintendent of the Salem Hospital, aged 76, died, September 9

Thomas Joseph Cronin ⊕ Worcester, Mass., Baltimore University School of Medicine, 1898, on the consulting staff of the Fairlawn Hospital, aged 69, died, September 10, in the Memorial Hospital, of carcinoma of the sigmoid

Abraham A. Pless, Philadelphia, Temple University School of Medicine, Philadelphia, 1918, member of the Medical Society of the State of Pennsylvania, aged 47, died, October 8, in the Mount Sinai Hospital, of lymphatic leukemia

Harmon Arthur Staley, Schenectady, N. Y., Albany (N. Y.) Medical College, 1891, member of the Medical Society of the State of New York, aged 70, died, September 21, of cerebral hemorrhage and arteriosclerosis

David Jacob Hyman, New York, College of Physicians and Surgeons, Medical Department of Columbia College, New York, 1895, on the staff of the Beth Israel Hospital, aged 62, died, October 3, of coronary thrombosis

Oscar Lee Ashby Torbett, Marlin, Texas, Atlanta (Ga.) College of Physicians and Surgeons, 1909, member of the State Medical Association of Texas, aged 60, died, September 13, of agranulocytopenia and septicemia

Augustus Burt Coolidge, Washington, D. C., Howard University College of Medicine, Washington, 1884, aged 78, died, September 22, in the Emergency Hospital, of hemorrhagic pancreatitis and right pyonephrosis

John Eastman Belding, Worcester, Mass., Harvard University Medical School, Boston, 1902, served during the World War, aged 62, died suddenly, September 16, in Northfield, of coronary occlusion.

Charles Frederick Culley, Cleves, Ohio, Eclectic Medical College, Cincinnati, 1918, aged 41, died, September 2, in the Deaconess Hospital, Cincinnati, of cerebral and pulmonary edema and acute nephritis

Frank Boogher ⊕ St. Louis, University of Virginia Department of Medicine, Charlottesville, 1895, served during the World War, aged 69, died, September 2, in the Barnes Hospital, of heart disease

John Woodson Gillespie, Sherman, Miss., Memphis (Tenn.) Hospital Medical College, 1903, member of the Mississippi State Medical Association, aged 61, died, August 24, of coronary thrombosis

Leonard Charbonneau, Ogdensburg, N. Y., School of Medicine and Surgery of Montreal, Que., Canada, 1891, aged 72, died suddenly, October 1, in the Hepburn Hospital, of coronary thrombosis

Charles P. Brown ⊕ Oklahoma City, Okla., University Medical College of Kansas City, Mo., 1900, on the staff of the Oklahoma City General Hospital, aged 68, died, September 13, of heart disease.

George Washington Conterno, New York, Long Island College Hospital, Brooklyn, 1891, aged 66, died, September 9, in the Veterans' Administration Facility, of myocarditis and arteriosclerosis

Hosea August Vise, Benton, Ill., St. Louis College of Physicians and Surgeons, 1905, member of the Illinois State Medical Society, aged 52, died, September 16, of carcinoma of the rectum

Thomas Foster Cleaver, Lebanon, Ky., University of Louisville Medical Department, 1887, member of the Kentucky State Medical Association, aged 69, died, October 9, of heart disease

William J. Childress, Greenwood, Ind., Hospital College of Medicine, Louisville, 1900, aged 61, died, September 5, of pulmonary edema, acute cardiac dilatation and cirrhosis of the liver

Ernest de Mary Brumback, New York, Hahnemann Medical College and Hospital of Philadelphia, 1899, aged 61, hanged himself, October 2, at his home in White Plains

John H. Buschemeyer, Louisville, Ky., University of Louisville Medical Department, 1891, formerly mayor of Louisville, aged 65, died, October 7, of coronary occlusion.

Lyme Harry Blanchard ⊕ Oakland, Calif., University of Vermont College of Medicine, Burlington, 1895, aged 62, died, September 5, of cerebral hemorrhage and myocarditis

Daniel A. Carlyle, Alba, Mo., McGill University Faculty of Medicine, Montreal, Que. Canada, 1901, aged 64, died, September 27, of paralysis agitans and arteriosclerosis.

Thomas R. Whitley, Douglasville, Ga., Atlanta Medical College, 1876, formerly member of the state legislature and mayor of Douglasville, aged 80, died, September 3

Cicero Minor Nichols, Houston, Texas, Medico-Chirurgical College of Philadelphia, 1899, aged 77, died, July 25, of injuries received when struck by an automobile.

Mary J. Henry Aiton, Summer Hill, Ill., Northwestern University Woman's Medical School, Chicago, 1901, aged 70, died, September 1, of multiple neuritis

John Rufus Allen, Haldton, Okla., Hospital College of Medicine, Louisville, Ky., 1905, aged 54, was found dead, September 18, of cerebral hemorrhage.

Sebastian Stol ⊕ Chicago, College of Physicians and Surgeons of Chicago, 1892, aged 66, died, October 27, in St. Elizabeth's Hospital, of coronary sclerosis

John B. Burford, Rosebud, Texas, Tulane University of Louisiana Medical Department, New Orleans, 1890, aged 70, died August 15, of diabetes mellitus

John Calhoun Harris, New Hope, Ala., Chattanooga (Tenn.) Medical College, 1900, aged 61, died, July 14, in Albertville, of cirrhosis of the liver

Jay Wesley Hollis, Mullins, S. C., Lincoln Memorial University Medical Department, Knoxville, 1912, aged 46, died, July 14, in Greenville, of pellagra

Alfred Harris Abernathy, Erin, Tenn., Vanderbilt University School of Medicine, Nashville, 1888, aged 72, died, September 17, of heart disease

Upton Hollifield Kelley, Waynesboro, Ga., University of Georgia Medical Department, Augusta, 1907, aged 54, died, July 10, of chronic myocarditis

George W. Wallace, Middletown, Ind., Medical College of Indiana, Indianapolis, 1895, aged 69, died, September 4, of acute dilatation of the heart

Samuel Martin Fraser, Westmount, Que., Canada, Western University Faculty of Medicine, London, Ont., 1889, aged 65, died, August 31

Lewis A. Thomason, Texarkana, Ark., Memphis (Tenn.) Hospital Medical College, 1894, aged 78, died, July 10, of heart disease.

James Edward Hanna, Ottawa, Ont., Canada, Queen's University Faculty of Medicine, Kingston, 1886, aged 74, died, August 30

Hartley Orin Baker, Los Angeles, Denver and Gross College of Medicine, 1906, aged 65, died, September 28, of heart disease

Pink Howe Howard, St. Louis, St. Louis College of Physicians and Surgeons, 1914, aged 49, died, September 7, of heart disease.

John L. Cox, Lyons, Ind., Hospital College of Medicine, Louisville, 1898, aged 74, died, August 25, of arteriosclerosis

William Marcus Lee, Fair Oaks, Calif., St. Louis University School of Medicine, 1927, aged 31, died, August 5

Joseph L. Russell, Chicago, Jenner Medical College, Chicago, 1902, aged 65, died, October 28, of carcinoma

William Cannon Kennedy, New York, Missouri Medical College, St. Louis, 1880, aged 79, died, September 13

Bureau of Investigation

NEW SCIENCE INSTITUTE

A Fraudulent Rupture Cure Debarred from the Mails

For some years one John G. Homan of Steubenville, Ohio, has been a mail-order quack. He is not a physician, a pharmacist or a chemist, yet he has put out pieces of quackery that have been sold under the implied claims that they would cure "prostate trouble" and rupture. In the prostate field Homan has operated under the name of "Electro Thermal Company," which puts out a device that is essentially a rectal dilator with a thermostat attachment that permits the device, when placed in the rectum, to have its temperature raised by the electric current. In the same field Homan has also operated under the trade name "Harmless Remedy Company" which put out, among other things, a rectal suppository containing a mixture of substances which, when a small amount of water was added to them, would generate heat.

In the "rupture cure" field he has done business under the trade name "New Science Institute," which put out a truss that was sold under the claim that it was not a truss and to which has been given such fancy names as "Magic Dot," "Suction-Cell," "New Science Retainer," etc.

In 1929 the Federal Trade Commission issued a complaint against John G. Homan, connected with his New Science Institute quackery. After an extended hearing, the Federal Trade Commission issued a Cease and Desist Order in November 1931. Under this Homan was ordered to cease exaggerating the value of his so-called system and disparaging the products or methods of treatment offered by competitors. He was ordered to cease alleging that by the use of his device, the so-called Magic Dot, every reducible rupture could be supported or cured in a considerable proportion of the cases.

Homan evaded the orders of the Federal Trade Commission, by the usual advertising method of lying by implication instead of directly. As Homan's quackeries have always been carried on through the agency of the United States mails, the Post Office Department turned its attention to him in connection with the rupture-cure fake. In November 1934 the New Science Institute and John G. Homan were called upon to show cause why a fraud order should not be issued against them. A hearing which lasted three and a half days was held in January 1935 at the conclusion of which Homan and his so-called Institute were granted three weeks in which to submit a brief. Following the submission of the brief the Hon. Karl A. Crowley, Solicitor for the Post Office Department, carefully reviewed all of the evidence in the case and summed it up in an extensive memorandum addressed to the Postmaster General. From the Solicitor's memorandum and the files of the Bureau of Investigation the following data have been obtained:

The New Science Institute was a trade name used by John G. Homan and his wife operating as partners. It was started originally as a department of Homan's prostate-cure quackery

and operations were begun under the name of New Science Institute in 1923. Homan has advertised extensively and the files of the Bureau of Investigation of the American Medical Association contain large display advertisements from the following newspapers and magazines that have appeared at one time or another during the period that the New Science Institute has operated. Among the newspapers that have carried New Science Institute advertisements were the following: *Chicago Herald and Examiner*, *Daily Times*, *Chicago Democrat* and *Chronicle*, *Rochester (N. Y.) Daily Times*, *Davenport, Iowa Illinois States Register* and *Toledo News-Bee*. Some of the magazines that sold space to this piece of quackery were *Physical Culture*, *Popular Mechanics*, *Real Detective*, *Pathfinder Psychology*, *Strength*, *Real America*, *Shrine Magazine*, *Kivuanis Magazine*, *Modern Woodman Magazine*, and *Modern Living*.

The advertisements were invariably illustrated with many of them showing women in bathing suits doing acrobatic stunts, and implying that the women were ruptured but could do these tricks because they wore Homan's device. At the hearing Homan admitted that the persons shown in such advertisements were professional models and that he had no knowledge of whether or not they were ruptured or were, in fact, using any appliance.

In common with all mail-order quacks, Homan published testimonials. He preferred the publication of such testimonials with the statement that they were "representations of the writers of them and not us." As Solicitor Crowley pointed out, although the New Science Institute attempted to escape responsibility for publishing these testimonials by stating that they were representations of the writers, the printing of them was manifestly designed to, and did actually, convey the impression that the purchasers of the Magic Dot or the Suction Retainer, or whatever name the piece of quackery happened to go by at that time, would secure the curative and other results claimed by the testimonial writers. Homan

also admitted during the hearing that he had unfavorable letters from persons who had bought his device, and when asked why he did not publish any of these, replied "That would be foolish."

While Homan declared at the hearing that his appliances were sold for "reducible" ruptures only, he admitted on questioning that they were actually furnished in cases in which the question of reducibility was undetermined and evidence was submitted to show that the device was sold in one instance to a person who described his hernia as being as large as a goose egg!

The New Science Retainer, as Homan's device was called more latterly, was a flat circular, rubber pad having about the approximate circumference of a silver dollar, it was about three-quarters of an inch thick and had a number of shallow indentations on its surface. Although Homan's advertising claimed that his appliance worked without belts the New Science Retainer actually had attached to its outer surface a catch for the express purpose of enabling it to be attached to

Beware the Small Rupture that Doesn't Bother Much

Light as a Feather Yet Holds Rupture!

An Ohio Salesman is now helping Nature rescue thousands of rupture victims. No more surgery. No more embarrassing contractions of ancient times. No more appliances worn without embarrassing bulk, without leg straps or springs or laces or leathers. You will be astonished. He may show, his revolutionary medicine will overcome. His test after actually includes an free appliance sent to you absolutely FREE. Mail coupon today for the most astounding rupture information you ever read. It is Free and will come in plain cover.

PERSONAL GUARANTEE
Suction-Cell Retainer must give the results that you require or you may return it. If your rupture is not actually held, promptly reduced in size during the first trial we offer you a full refund. If you do not need it back and demand the return of your money we agree. If 10 days trial are not enough, write us and we will extend the trial to 30 days or even longer.

NEW SCIENCE INSTITUTE
2000 New South Bldg.
Birmingham, Ala.

Now rupture victims can abandon the painful and discomfort of your truss. Science has at last developed a comfortable appliance of tremendous support for every rupture sufferer. This device is called "Suction-Cell Retainer." It has been developed and perfected as a result of having made many close studies rupture appliances. With it comes an extraordinary natural help.

in bulk and weight that even most rupture victims who have not known they were ruptured.

Reasonable in price. And you don't need to wait forever for results!

Get Free Offer
Send no money. Just mail coupon and you will receive our famous best selling rupture, together with our attractive bonus-size offer of special FREE appliance, all in plain packet. I will open your eyes.

Reproduction (greatly reduced) of a full page advertisement that appeared in *Kivuanis Magazine* September 1932

a belt to which Homan gave the name "Duogirdle." In spite of this, Homan represented, iterated and reiterated throughout his advertising that belts and leg straps were unnecessary in connection with the utilization of his so-called system.

Much was made by Homan in his advertising of what he called "Seaver Essentials," which was said to be the adoption of a method of treatment by which Dr. J. W. Seaver of "a great Eastern University" was alleged to have cured seven out of ten persons of rupture. These so-called Seaver Essentials were furnished by Homan in a booklet entitled "How to Aid Nature in Rupture—Quickly." They consisted merely of descriptions of a number of movements of the arms, legs and torso, including instructions for the massage of the area surrounding the rupture, and advice for the relief of constipation. It appeared that Homan appropriated the so-called Seaver Method from an old textbook. There was a Dr. J. W. Seaver who forty years ago was associate director of Yale University gymnasium, he died twenty years ago. A physician who had been associated with Dr. Seaver during his connection with the gymnasium furnished the Post Office Department with some facts in the matter. It appears that Dr. Seaver carried on some emergency medical oversight in a few students, among whom some few cases of rupture were noted, and, not being satisfied with the available trusses, the doctor devised a rubber attachment of his own and, in collaboration with his associates, also arranged a series of safe exercises. Dr. Seaver's associate stated that the doctor never cured seven out of ten cases of rupture, as Homan had claimed, and that it was doubtful if he had, in fact, ever cured a single case. It was further shown that the brochure written by Dr. Seaver was hopelessly outdated, a view that was substantiated by medical expert testimony adduced by the government at the hearing.

It was brought out at the hearing, also, that no physicians were employed by the New Science Institute, and even a so-called truss fitter that was employed by the New Science Institute admitted during the course of testimony that he was quite unable to answer questions of a medical nature with respect to rupture. Homan's own attorney also had to concede that a number of answers given by Homan himself to similar questions were erroneous.

Aside from the quackery involved in the sale of Homan's device, there was also commercial trickery. The Solicitor for the Post Office Department stated that it was proved that it was the established practice of the New Science Institute to send the so-called free Activator Model and leg strap in a separate package so sealed as to prevent a trial or even a complete examination. Then there was printed on the outside of the wrapper a warning to the effect that the contents could not be returned if the seal was broken, but there was a careful avoidance of any statement that such breaking of the seal would result in the loss of the right of refund. It was shown in a number of cases that many persons who had purchased the so-called System and found both the sealed and unsealed portion thereof unsatisfactory were denied the return of their money on the ground that they had broken their "contract." In fact, Homan admitted at the hearing that his concern endeavored to escape making refunds whenever possible, and he also admitted that it was probably true that the statements in his literature were calculated to induce patrons to open the sealed packages. It was brought out, further, at the hearing that Homan had a "stool-pigeon" described in the quack literature as "Herbert Ayers, Box 402, Wheeling, W. Va." Homan when questioned, could not say who Herbert Ayers was. The postmaster at Wheeling, W. Va., however, reported that Box 402 was rented by one Carl Schumann, who was an employee of the New Science Institute.

The government had no difficulty in showing that the claim that the Homan device would cure rupture was false and fraudulent. Mr. Crowley closes his memorandum to the Postmaster General with the statement that he recommended that a fraud order be issued against the New Science Institute and its officers and agents as such. The Postmaster General notified the postmaster at Steubenville, Ohio, to return all letters and other mail matter that came addressed to the New Science Institute to the senders with the word "Fraudulent" plainly written or stamped on the outside of such letters. The order went into effect April 25, 1935.

Queries and Minor Notes

ANONYMOUS COMMUNICATIONS and queries on postal cards will not be noticed. Every letter must contain the writer's name and address, but these will be omitted on request.

STITCH ABSCESS—FOOD PRESERVATIVES— AUTOGENOUS VACCINE

To the Editor—Would you kindly give 1 The correct treatment of a stitch abscess according to various stages 2 Names and dosages of several food preservatives 3 Practical method of preparing an autogenous vaccine from a pustule and a pathologic urine. Please omit name. M.D., Michigan.

ANSWER.—1 A stitch abscess is one arising round or limited to the region of a suture. The term is used in most hospitals improperly to cover any infection of a wound. In the early stages there may be some redness round the approximating stitches of a wound. If examined microscopically, a small abscess probably could be demonstrated round the stitch. Most of these stitch infections terminate with little gross suppuration, and healing is prompt after removal of the stitches. As soon as redness is noted round skin sutures, warm moist compresses of boric solution should be applied. Usually the stitches that are most involved, especially if interrupted in type, should be removed. If the infection has progressed to the stage of gross abscess about the sutures, the same treatment will usually be satisfactory, as the pus usually drains out through suture holes. In other instances the infection has spread from the stitches to the edges of the wound with the development of free pus between them. The skin may look perfectly healed on the surface, with little redness, or there may be considerable inflammation with induration about the wound. Warm boric compresses should be applied if there is considerable induration without free pus. When free pus can be demonstrated or is suspected the edges of the skin should be separated by a sterile probe and if pus is present it may be drained by the removal of a few stitches. If there tends to be a pocket, a small rubber drain may be inserted or the superficial tissues opened widely. In the presence of any infection of a wound there is usually delayed healing of all the tissues with great danger of separation of the wound because of early digestion of the catgut sutures. Wide tension sutures should always be used and adhesive straps applied to bridge the wound on the removal of any sutures to prevent hernia or excoriation.

2 The bureau of chemistry of the U. S. Department of Agriculture determines the use of any substance used as a food preservative. Inquiry and access to bulletins should give further information than can be given here. Probably the most important preservative is sodium benzoate. Under President Theodore Roosevelt a board of consulting experts from three universities studied the effects of sodium benzoate on man under careful experimental conditions. They all concluded essentially that sodium benzoate in small doses (under 0.5 Gm. daily) mixed with food was without deleterious or poisonous action and is not injurious to health, sodium benzoate in large doses (up to 4 Gm. daily) was found not to be injurious to health, and the admixture of sodium benzoate with food in small or large doses was found not to affect injuriously or impair the quality or nutritive value of such food. The secretary of agriculture ruled that sodium benzoate was permissible for use as a preservative of food if so stated on the label. Manufacturers of food products which in their view require the use of a preservative are in general content with 0.1 per cent of sodium benzoate. In eating such a preserved food the consumer would need to take 300 Gm. daily, or nearly two thirds of a pound, to ingest an amount of sodium benzoate equal to the minimal dose of 0.3 Gm. daily used in the experiments on man. The large doses given to human subjects ranged from 0.6 Gm. to 4 Gm. daily over one month and even larger doses were given. The chief objection to the use of chemical preservatives is that their addition makes it easier to use inferior or partially spoiled raw materials and it prevents the natural fermentation and spoilage following insatisfactory conditions of handling food. The use of sulphur dioxide, copper sulphate, alum, gluside, borax or borates has been referred to the board, whose further reports were not available.

3 In the preparation of autogenous vaccine, the bacteria must be obtained without contamination. The surface of a pustule may be seared with a hot instrument or cleaned with an antiseptic solution that evaporates quickly, such as alcohol. The pustule is lanced or a sterile needle inserted and the pus obtained for growth. A specimen of urine must be obtained by catheterization after surgical cleansing of the field, by means of sterile instruments. Suitable mediums are inoculated and after growth

the bacteria are washed off in salt solution. They may be standardized by means of the Hopkins calibrated vaccine centrifuge tube. After centrifugation the salt solution is largely removed and the bacteria are suspended in 1 1000 merthiolate solution. They are placed in an incubator from four to six days and then tested for sterility. They are diluted as desired, usually from 100 million to 1 billion to a cubic centimeter for clinical use. An older method was to wash off the bacteria in salt solution and kill by heating to 57 C for half an hour. Bacteria may be counted directly with a hemocytometer, with the use of a dilute aniline dye such as an alcoholic solution of methylene blue. The bacterial suspension may be mixed with blood corpuscles and, after counting, their number may be estimated by determining the ratio between them. After standardization, they may be preserved in salt solution to which 0.5 per cent of phenol (carbolic acid) is added.

PANCREATIC EXTRACT IN CLAUDICATION

To the Editor—In Queries and Minor Notes in THE JOURNAL March 23 you mention a pancreatic extract insulin free used in claudication. I have been unable to get any information from New York dealers in reference to this product. Can you tell me where it may be obtained?

EDWARD S. NEWELL, M.D., Pelham Manor, N.Y.

ANSWER.—Various tissue and urine extracts have been used in intermittent claudication. Intramuscular administration has been effective in some cases with the active extracts. Two pancreatic extracts are now available. The extract isolated by Frey and Kraut from urine was first called kallikrein, later padutin. A preparation called padutin is now made from pancreas and can be obtained from the Winthrop Chemical Company, New York. Pancreatic Tissue Extract No. 568, produced by Sharp and Dohme, Baltimore, has been used effectively in some cases. More recently an active principle has been found in other tissues. Several skeletal muscle extracts have been reported to be useful, namely, Myoston and MAP (muscle adenosin phosphoric acid) prepared by Dr. Henning of Berlin. A tissue extract said to be equally effective is Heart Muscle Extract, prepared by Eli Lilly Company in Indianapolis. These extracts are entirely in an experimental stage. They have not been accepted by the Council on Pharmacy and Chemistry of the American Medical Association. Controlled clinical trials have indicated that the active principle or principles of these extracts affects the pain of contracting muscle in the presence of a diminished blood supply. It is not certain that the active principle is the same in all cases and it appears that the principle or principles of these preparations may not properly be considered hormones.

THE POLARITY OF CHEST LEADS

To the Editor—Probably many physicians have wondered why electrocardiograms made by chest leads appear to be upside down. P, R and T of normal records all inverted and S alone upright. The answer is that some one started making them that way and others have followed the lead. If the first news reel showing Chinese scenes had been exhibited upside down because the producer thought that would insure recognition of the part of the earth portrayed it is not unlikely that all subsequent films from the antipodes would by force of cinema convention necessarily be shown in the same confusing fashion. For myself I prefer to see a normal P, R or T wave made by any derivation erect and healthy looking. Made by the inverse polarity they look sick. In spite of some criticism on the score of unconventionality I have insisted in my own hospital service on the use of the normal polarity. Until recently however it had not seemed to me a very serious matter for physicians as well as dentists can interpret a mirror image. But now I observe it is becoming customary to call the initial downward ventricular deflection a Q wave. This is serious confusion for the large downward deflection is unquestionably an R wave upside down, the true Q wave is usually entirely lacking. But if present what shall it be called? Since chest leads have been in use for only a relatively short time the pattern of these deflections has not yet become stereotyped in the medical mind as is the case with the standard leads. It is therefore not too late to reform. The obliging quartz fiber will deflect as willingly the other way if one will only interchange the lead wires.

FREDERICK H. HOWARD, M.D., New York

ANSWER.—Many have had the same reaction as that expressed in this communication to the introduction of the inverted complexes P, QRS and T waves in the precordial lead commonly called lead 4 in normal individuals. Doubtless some have been on the verge of initiating a campaign similar to that suggested here to reverse the lead points so that the chest lead will be normally composed of upright P, QRS and T waves, but later reflection has made it seem desirable to retain the precordial lead or lead 4 as proposed by several of those originally urging its routine adoption. The chief reason for this change of view being that, as commonly taken now, lead 4 is easily distinguished from the other leads, and since it is a newly introduced

lead it is well to have it readily distinguished from the other three. Practice makes one quite familiar with the inverted complexes and after the original irritation produced by seeing the upside down waves has passed one becomes content even with the appearance of the curve. Furthermore, so much has already been written during the last year or two about lead 4 as ordinarily taken that it would create a considerable bother and confusion to make the change.

However the criticism with reference to the nomenclature of the QRS wave is pertinent. As stated the Q is really not a Q but an inverted R, and the R is not an R wave but an upright S. The same criticism holds for the nomenclature of the QRS waves in the ordinary leads, and this was emphasized in a recent paper by Sylvester McGinn and P. D. White (The Duration of the QRS Complex in the Normal and in the Abnormal Electrocardiogram, *Am Heart J* 9:642 [June] 1934). McGinn and White have suggested a way out of the difficulty in their note on nomenclature at the end of the paper. They have advised that a more satisfactory method of describing the QRS complex would be to state positive and negative deflections by appropriate signs with amplitudes expressed in millimeters, thus QRS might equal $-2 +12, -5$, without Q, R and S being specified separately. The same procedure could easily be applied to lead 4.

RUGGLES' CREAM

To the Editor—Can you find for me in some of the formularies available in your office the composition of so-called Ruggles' Cream a mixture used on the hands?

M.D. Chicago

ANSWER.—The A. M. A. Chemical Laboratory inquired of Melvin & Badger Company, the manufacturers of this cream, whether or not the product was secret in composition, and if not, what was the quantitative statement of ingredients. The firm replied:

The Melvin & Badger Company Ruggles' Cream Formulae was originated by this company for Dr. Ruggles of Rochester, New York and Dr. Charles J. White of Boston and we do not feel disposed to furnish the composition to anyone.

Inquiry was then made of Dr. E. Wood Ruggles, who has kindly supplied the following information:

In reply to your communication to me regarding the Ruggles' Cream I wish to state most emphatically that I have never received one penny of compensation from any firm engaged in making it. I presume the Melvin & Badger Company prefer to keep the working formula to themselves as they sell a great deal of the cream which they explain by saying that no other drug firm has been able to manufacture the cream as it should be done. Or perhaps they thought no one should have the formula without obtaining it directly from me.

I published the working formula in the *Archives of Dermatology and Syphilology* some years ago and firms in various cities make a very fair cream. Most of them will not take pains to have the three component parts at exactly the same temperature when mixing them. I take pleasure in enclosing the formula used by the Company in this city and shall be glad to have you send it to any inquiring physicians or pharmacists always warning them that it is extremely difficult to manufacture properly.

"I think I should add that it would be well to write any one inquiring about the formula that they should only have it manufactured by an especially fine pharmacist and one who takes pride in his work. Other wise it will be a failure."

The formula supplied by Dr. Ruggles is as follows:

| | Gm or Cc |
|-----------------------|----------|
| Powdered stearic acid | 75 |
| Potassium carbonate | 15 |
| Distilled water | 320 |
| Powdered borax | 5 |
| Quince jelly | 75 |
| Distilled water | 100 |
| Powdered zinc oxide | 10 |
| Glycerite starch | 400 |

Melt the stearic acid. At the same time dissolve the potassium carbonate in 320 cc of distilled water and heat to about 170 F on water bath. Bring stearic acid to the same temperature and mix them. Continue this temperature on the water bath with occasional stirring until the reaction is perfectly complete.

Dissolve the powdered borax in 100 cc of distilled water, add the quince jelly and heat on water bath to about 170 F. Add this mixture to the first which should be at the same temperature and again leave on water bath until reaction is complete.

Heat the glycerite of starch to the same temperature, stir in the powdered zinc oxide with a glass stirring rod and add to the other mixture, stirring occasionally.

Let cool and add perfume (Oil Ylang Ylang recommended).

The most important essential is to employ a perfect glycerite of starch. Use Kingford's or other suitable grade of corn starch and U. S. P. Glycerin and make it up fresh for each batch.

Also essential is to have all three batches at exactly the same temperature when mixing them.

POSSIBLE LEAD POISONING

To the Editor—May I take the liberty of asking your opinion concerning a case of suspected lead poisoning which recently came under my care. Briefly, the case is as follows: A man, aged 32, a Mexican, employed for ten years as a sprayer (using black paint said to contain no lead) and for the past two and one-half years as an enameler (enamel containing frit—ground glass—in which is found a certain amount of lead—about 27 per cent according to report), enjoyed good health and had never been ill or had an acute infection of any kind and his family and marital histories were negative. During the past two years he had complained of occasional headache, usually frontal and in the last two weeks of his employment these headaches became so severe that he was obliged to quit work. In addition he complained of vertigo, blurring of vision, weakness, anorexia and vomiting, loss of weight and a recent nocturia. There was no history or stigmas of syphilis, and the Wassermann reaction was negative. On examination he was found to be in a state of fairly good nourishment but appeared pale (noticeable even with the dark skin). He was found to present most of the elements of a chronic nephritis with hypertension and evidence of albuminuric retinopathy, the picture of a so-called malignant hypertension, and within ten weeks the patient died after presenting for a week the picture of uremic poisoning. The blood pressure on first examination was 206 systolic, 150 diastolic. The urine always contained much albumin and some casts hyaline and granular, with occasionally a few red blood cells. The specific gravity was usually about 1.010. The first quantitative lead determination on the urine (taken about three weeks after the last day of exposure to this metal while at work) showed an excretion of 0.17 mg to 1.500 cc, or about 0.12 mg per liter. After three days on a "deleading" regimen, urine was again collected for twenty-four hours and showed an excretion of 0.202 mg per liter or nearly double the former reading. After an interim of about six weeks on a regular diet (in which calcium had not been restricted) the excretion was a little more than 0.12 mg per liter and this was the last such test made. No test was made of the lead content of the feces or blood serum. The patient presented practically none of the so-called classic symptoms of chronic plumbism. There was at first no anemia, although all subsequent blood counts disclosed a moderate anemia and at no time was there stippling observed. A reticulocyte count was not made. There was no lead line in the gums, but neither was there any pyorrhea or carious teeth clinically or roentgenographically. There were at no time symptoms of colic or of marked constipation, and no palsies were noted. The deep reflexes were increased however and toward the close there were muscular twitchings and protracted hiccuping. Vomiting was quite a prominent symptom throughout and headache chiefly frontal and suboccipital was almost constant and frequently severe. There was complaint of some muscle pain in the extremities but no evidence of muscular weakness or palsy. He had no convulsions and was never in deep coma although he was semicomatose during the last two days. I trust that I have not omitted anything of great importance in this brief history of the case.

The question that arises specifically in my mind and concerning which your opinion would be greatly appreciated is this: In the absence of a history of any acute infection in the absence of any demonstrable foci of infection in teeth, tonsils, sinuses or prostate, in the absence of a familial history of hypertensive disease with a history of contact with lead over a period of several years with an onset of ill health dating back only two years but not disabling until a month or two preceding his gradual demise and with the rather meager observations suggesting chronic plumbism,

1. Could this be a case of chronic plumbism?
2. Is it likely that it was chronic plumbism?
3. Is it feasible that a so-called normal person not in intimate contact with lead could
 - (a) Show the amount of lead excretion found in this case (0.12 plus mg per liter of urine)?
 - (b) Show an increase such as this (0.202 mg per liter) after a few days on a deleading regimen? (Note: In addition to the restricted calcium diet the patient was given phosphoric acid by mouth but vomited after nearly each dose so ammonium chloride was substituted, and viosterol was also given orally.)
4. Have you knowledge of patients who have died of chronic plumbism who have shown no greater amounts of lead excretion in the urine than this case did?

I shall truly be grateful to you for an expression of your opinion in this matter.

P. K. EDMUNDS, MD, Los Angeles

ANSWER—The question that this communication propounds is essentially as follows: Can a small exposure to lead account for a malignant hypertension and prompt death from kidney insufficiency? That lead causes nephritis is often suggested in the literature, but the evidence for this is not satisfactory. There are two investigations that are suggestive. Workers with Blair Bell noted a small quantity of albumin and casts after the injection of lead intravenously. This was given for the treatment of cancer. This was an evidence of small kidney damage in spite of flooding the organism with lead. Dr. L. J. Nye published an article (*M. J. Australia* 2:145 [Aug. 3] 1929) which showed that children who had had lead poisoning had a high incidence of chronic nephritis.

The patient described in the query had an excretion of lead slightly greater than so-called normal. This indicated that he had absorbed a little more lead than the normal individual, but without evidence in the blood or other signs it would be difficult to make the diagnosis of lead poisoning. One may well make the diagnosis of lead absorption, but to link the

severe renal damage to chronic plumbism would hardly seem justifiable. There is no record of a patient dying of chronic plumbism who did not show greater amounts of lead excretion than this patient showed.

PAIN IN SHIN BONES AND CIRCULATORY DISTURBANCE IN LEGS

To the Editor—Could you suggest a diagnosis or further studies to be carried out on the following case in order to establish a diagnosis? A woman aged 70 complains of pain in the shin bones. The trouble started about five years ago and was at first intermittent but has now progressed to the point where the pain is constant and at times very severe. It is characterized as a dull ache in both tibiae, extending from the ankles to the knees. The pain is not related in any way to exercise or physical activity. The feet and toes are cold. The greatest relief is obtained by putting the legs in hot water. Physical examination is negative. The sinus teeth and mouth are normal. The heart is normal, and the blood pressure is 154 systolic, 74 diastolic. The lungs are clear, the abdomen is normal and the liver and spleen are not enlarged. The reflexes are equal and hyperactive. There is a normal plantar reflex and a good pulse in both dorsalis pedis and posterior tibial arteries. There is moderate sclerosis of the brachial arteries. The plantar arches are normal. Roentgenograms of the legs are negative and the arteries cannot be seen. The Wassermann reaction is negative. Examination of the blood reveals hemoglobin 102 per cent (Sahl), red blood cells 4,450,000, differential 52 per cent polymorphonuclear leukocytes, 33 per cent lymphocytes, 2 per cent eosinophils, 3 per cent basophils, 4 per cent transitional. Examination of the urine is negative, basal metabolism is -8 per cent. The patient has a stable nervous system and the trouble is not imaginary. Any suggestions as to diagnosis or treatment will be appreciated. Please omit name. M.D., New York.

ANSWER—The diagnosis in this case is difficult. The coldness of the feet would suggest a circulatory disturbance, but the fact that the arteries in the feet pulsate freely would probably rule out Buerger's disease (thrombo-angiitis obliterans). The pain in the tibiae would suggest a beginning Paget's osteitis deformans, but the roentgen evidence seems to be lacking. Osteosclerosis (Albers-Schoenberg), or its opposite, acute bone atrophy, can usually be determined by roentgen examination.

The state of circulation in the feet should be determined by the rate of heat loss, the surface temperature, and the tests for capillary sufficiency. The sclerosis of the brachial arteries suggests a similar change in the arteries of the leg.

Thick woolen stockings should be worn, and diathermy should be used on both legs. Large quantities of water should be drunk daily, and a low protein diet should be enforced.

RENAL GLYCOSURIA

To the Editor—A white woman aged 48 came to me complaining of a loss of 10 pounds (4.5 kg.) during the three months preceding her visit, nervousness, fatigue and irritability. There was a history of occasional episodes of spastic colitis over a five year period, the last attack occurring in March 1935. Physical examination including fluoroscopy and proctoscopy was negative. The red blood cell count and hemoglobin were within normal limits. The Wassermann test was negative. The basal metabolic rate was plus four. The only positive finding was a two plus urinary sugar. The fasting blood sugar was 104 mg per hundred cubic centimeters of blood. A sugar tolerance test was done and found to be normal. The patient has been on a diet of 150 Gm. of carbohydrate and 80 Gm. of fat for the past two weeks and has continued to spill from one plus to two plus sugar in specimens taken two hours after meals. The urinary sugar is dextrose. Will you kindly advise me on the following: 1. Am I correct in calling this a case of renal glycosuria? 2. What is the dietetic management of renal glycosuria? 3. What other conditions might be considered in a differential diagnosis? 4. What is the prognosis as regards the appearance of diabetes mellitus in a patient with renal glycosuria? Kindly omit name and address.

M.D. New Jersey

ANSWER—1. If the blood sugar determinations made in the sugar tolerance test were reliable, this case is probably one of renal glycosuria.

2. Patients with true renal glycosuria are usually not benefited by dietary restrictions. They require no treatment.

3. Other possibilities are that the reducing substance in the urine is something other than dextrose. Fructosuria, pentosuria, galactosuria, glycuronic acid and homogentisic acid should be considered. The identification of dextrose depends on a positive fermentation test and dextrorotation in the polaroscope. The methods for identifying other reducing substances in the urine can be found in the manuals of clinical diagnosis.

4. The experience of Powelson and Wilder (Powelson, H. C., and Wilder, R. M. Innocent Glycosuria, *THE JOURNAL*, May 9, 1931, p. 1562) with eighty-two cases of renal glycosuria followed for a long period did not indicate any instance of the development of true diabetes mellitus. The prognosis in renal glycosuria is apparently entirely benign.

MAMMARY TUMOR IN MALE

To the Editor—A married man, aged 33 weighing 170 pounds (77.1 Kg.), consulted me about pain in the right breast. He states that he first noted this about two years ago when he had gained about 30 pounds (13.6 Kg.), and since then when somebody accidentally touches him, or if he brushes against something, he notices the pain. Otherwise the pain is not noticeable. The past history is essentially negative. He states that his breasts were always larger than other boys and this was called to his attention on numerous occasions. Both parents are living and well. He has two sisters and a brother apparently healthy. A thorough physical examination including urinalysis and blood examination was negative with the exception of the right breast which revealed a well padded male mamma slightly larger than the left. It is freely movable with no retraction of the nipple and no enlargement of the axillary nodes. Pressure on the nipple causes a pain, but not elsewhere. There is palpable beneath the nipple in the substance of the breast a firm circular area of induration however a similar but smaller induration nonpainful, can be palpated in the left breast. Local anodyne applications are of no avail. He is getting worried for fear the pain is due to a malignant condition. Your suggestions as to the probable cause and treatment would be greatly appreciated. Kindly omit name.

M D Illinois

ANSWER.—The first thing is to ascertain whether there is not a tumor of the testicle. Teratoma in this region may cause enlargement of the breast. If not, an exploratory operation should be done, for while it is probable that only a fibroadenoma is present—the youth of the patient being strongly in favor of a benign hyperplasia—the mortality from carcinoma of the male breast is so high that no mammary tumor which persists more than a few weeks should remain without investigation.

RENAL COLIC AND INFECTION

To the Editor—A white man aged 30 had an attack of renal colic in August 1933. He passed several stones subsequently after which cystoscopy was done. At this time the pelvis were not dilated and kidney function was excellent. The renal function and general health remained excellent until April 1935 at which time the patient suffered a single attack of colic. At this time a flat plate revealed two stones in the course of the right ureter. To date the patient has been comfortable and has passed no stone. What is the advisability and advantage of having cystoscopy done again in this case? Please omit name and address.

M D New Jersey

ANSWER.—In view of the fact that this patient has no symptoms, a policy of watchful waiting is justified as long as the urine remains free from infection.

If, however, the patient again has an attack of renal colic, the urine shows infection, and a repeated roentgen examination shows no movement of the stones, or if the pyelograms show dilatation with perhaps suspension of function in the kidney, it is advisable to pass the cystoscope again, dilate the ureter with bougies and inject sterile oil into the ureter to aid in moving the stones down the ureter.

TRAUMA AND EPIDIDYMITIS

To the Editor—In Queries and Minor Notes in THE JOURNAL, May 4, page 1659 I note your answer to the questioner from Pennsylvania. Trauma may be an exciting cause of an acute attack of nongonorrheal epididymitis in a person who gives no history of a gonorrheal infection. Would it not be well to state this answer so as to rule out strain? I can conceive of a direct trauma being able to cause a localization or recrudescence of a latent disease but so frequently "lifting" is given as a traumatic etiology that I think it well to be specific. See article by Miley B. Wesson in THE JOURNAL Dec 15 1928 page 1857.

C F N SCHRAM M D Kingsport Tenn

ANSWER.—The question of strain, such as straining at stool or heavy lifting, does play a part as an exciting cause in acute epididymitis, whether gonorrheal or nongonorrheal. This was included in the term 'trauma'.

BURNING PAIN AND BLOOD CIRCULATION IN MOUTH

To the Editor—Can you tell me the cause and remedy for burning in the mouth and throat which is relieved by removing false teeth? Both of my patients with this condition are rather nervous types. One has even had a gold plate made but to no effect. The reaction of the saliva to litmus is alkaline. Urine examinations are negative. No blood work has been done. The sets of teeth of the two patients were made by different dentists. Both sets apparently fit well and one patient has had three sets. Please omit name and address.

M D Pennsylvania

ANSWER.—Almost without exception this burning is caused by an impaired blood supply, due to the pressure of the dentures over the anterior and posterior palatine foramina. Relief should be made in the impressions before the dentures are made. It might be possible to relieve these areas on the dentures that the patients are now wearing, but ordinarily it is difficult to make sufficient relief to eliminate the burning.

Medical Examinations and Licensure

COMING EXAMINATIONS

AMERICAN BOARD OF DERMATOLOGY AND SYPHILOLOGY. Written examination for Group B applicants will be held in various cities throughout the country March 14. Oral examination for Group A and B applicants will be held in Kansas City, Mo. May 11-12. Applications for written examination should be filed with the secretary before Jan 15. Sec. Dr. C. Guy Lane, 416 Marlboro St. Boston.

AMERICAN BOARD OF OBSTETRICS AND GYNECOLOGY. Written examination and review of case histories of Group B applicants will be held in various cities of the United States and Canada Dec 7. Sec., Dr. Paul Titus, 1015 Highland Bldg. Pittsburgh (6).

AMERICAN BOARD OF OPHTHALMOLOGY. St. Louis Nov 18. Asst. Sec. Dr. Thomas D. Allen, 122 S. Michigan Ave. Chicago.

AMERICAN BOARD OF ORTHOPAEDIC SURGERY. St. Louis Jan. Sec. Dr. Fremont A. Chandler, 180 N. Michigan Ave. Chicago.

AMERICAN BOARD OF OTOLARYNGOLOGY. Kansas City Mo., May 9. Sec. Dr. W. P. Wherry, 1500 Medical Arts Bldg. Omaha.

AMERICAN BOARD OF PEDIATRICS. St. Louis Nov 20. Sec. Dr. C. A. Aldrich, 723 Elm St. Winnetka Ill.

AMERICAN BOARD OF PSYCHIATRY AND NEUROLOGY. New York Dec 30. Sec. Dr. Walter Freeman, 1726 Eye St. N. W. Washington D. C.

AMERICAN BOARD OF RADIOLOGY. Detroit Dec 12. Sec. Dr. Byrl R. Kirklin, Mayo Clinic Rochester Minn.

ARIZONA Basic Science. Tucson, Dec 17. Sec. Dr. Robert L. Nugent, Science Hall University of Arizona Tucson.

CALIFORNIA Reciprocity. Los Angeles Dec 4. Sec., Dr. Charles B. Pinkham, 420 State Office Bldg. Sacramento.

CONNECTICUT Endorsement. Hartford, Nov 26. Sec., Dr. Thomas P. Murdock, 147 W. Main St. Meriden.

KANSAS Topexa Dec 10-11. Sec. Board of Medical Registration and Examination Dr. C. H. Ewing, 609 Broadway Larned.

KENTUCKY Louisville, Dec 3. Sec. Department of Health, Dr. A. T. McCormack, 532 W. Main St. Louisville.

MARYLAND Medical (Regular). Baltimore, Dec 10-13. Sec. Dr. John T. O'Mara, 1211 Cathedral St. Baltimore. Medical (Homeopathic). Baltimore Dec 10-11. Sec. Dr. John A. Evans, 612 W. 40th St. Baltimore.

NEBRASKA Lincoln Nov 19-20. Dir. Bureau of Examining Boards Mrs. Clark Perkins, State House Lincoln.

NORTH CAROLINA Endorsement. Raleigh Dec 9. Sec., Dr. Ben J. Lawrence, 503 Professional Bldg. Raleigh.

OHIO Columbus Dec. 3-5. Sec. State Medical Board Dr. H. M. Platter, 21 W. Broad St. Columbus.

OKLAHOMA Oklahoma City Dec 11. Sec. Dr. James D. Osborn Jr. Frederick.

TEXAS Houston Nov 18-20. Sec. Dr. T. J. Crowe, 918 Mercantile Building Dallas.

VIRGINIA Richmond Dec 11-13. Sec., Dr. J. W. Preston, 28 1/2 Franklin Rd. Roanoke.

WISCONSIN Basic Science. Milwaukee, Dec 21. Sec., Prof. Robert N. Bauer, 3414 W. Wisconsin Ave. Milwaukee.

California July Examination at San Francisco

Dr. Charles B. Pinkham, secretary, Board of Medical Examiners, reports the written examination held at San Francisco, July 9-11, 1935. The examination covered 9 subjects and included 90 questions. An average of 75 per cent was required to pass. One hundred and twenty-eight candidates were examined, 125 of whom passed and 3 failed. The following schools were represented:

| School | PASSED | Year Grad (1935) | Per Cent |
|--|--|------------------|----------|

Iowa June Examination

Mr H W Grefe, director, Division of Licensure and Registration, reports the written examination held by the Iowa State Board of Medical Examiners in Iowa City, June 4-6, 1935. The examination covered 8 subjects and included 100 questions. An average of 75 per cent was required to pass. Seventy-four candidates were examined, 73 of whom passed and 1 failed. The following schools were represented:

Book Notices

Modern Home Medical Adviser Your Health and How to Preserve It. Edited by Morris Fishbein. M D. Fabrikoid. Price \$9.50. Pp 905 with 140 illustrations. New York: Doubleday Doran & Company Inc., 1934.

The idea of a family health book is not new. For fifty years such volumes have decorated the library tables and sitting room tables in many homes along with the family Bible. However the home medical adviser of the past was full of scientific and hardly understandable diagrams of the human interior. It contained innumerable peculiar prescriptions which represented the superstitions of the past. It was usually written by a compiler who based his discussions on similar books that had gone before.

The present volume in no way resembles these earlier tomes. It represents the assembled views of men whose names have been associated with progress in the fields they discuss. Their contributions have been rewritten and reedited in many instances to make statements easily understandable by any fairly intelligent reader.

The book opens with a chapter on the choice of a physician, indicating the types of medical colleges, the importance of state licensure, the significance of membership in medical organizations and the development of the specialties. There follow chapters on the family medicine chest and first aid, and on the hygiene of women by Dr Fishbein. The section on sex hygiene has been prepared by Dr Thurman B Rice, whose name is associated with the development of a similar highly successful series in *Hygiene*. Dr J P Greenhill presents a chapter on the care of the mother before and after childbirth, and this is logically followed by a chapter on the care and feeding of the child and infant hygiene by Philip P Jeans of the University of Iowa and Frederick F Tisdall of the University of Toronto. The general prevention of infectious disease and the considerations of the individual infectious diseases, again by Morris Fishbein, occupy more than 100 pages. Next come discussions of the diseases of the heart and circulation by N C Gilbert and of digestion and digestive diseases by Drs Portis. Then the book proceeds through "The Kidney Its Diseases and Disturbances," by Philip S Hench, "The Blood and Its Disturbances," by Raphael Isaacs, "Deficiency Diseases" by Russell M Wilder and D L Wilbur, and "Allergy," by W W Duke. The glands are discussed by Drs Walter Timme and Oliver P Kimball, and Dr E P Joslin has contributed a notable hundred pages on diabetes. Dr Wingate M Johnson discusses blood pressure, both high and low, and cancer is discussed by Dr Francis Carter Wood. The hazards of industry are discussed by Dr C P McCord. The care of the skin and hair and nails is fully outlined by Dr Arthur W Stillians of Northwestern University Medical School. Then come sections on the subjects of diet, posture, the care of the feet, nervous and mental disturbances, and the care of the aged. These chapters are in turn written by Solomon Strouse, Tait McKenzie, Philip Lewin, George K. Pratt and Morris Fishbein.

The book is extensively illustrated with colored plates and with 136 photographs and outline drawings. Many of these drawings are of the outline humorous type so successful in *Hygeia*. The volume is beautifully printed with a wide column and a large page. The index, which itself occupies almost sixty pages, permits the user of the volume to find readily any topic that may concern him.

In the preparation of this book, self medication, except for the slightest ailments such as are now regularly treated by every one in his own home, is completely avoided. Indeed, the dangers of self medication are emphasized throughout the book. However, the intelligent reader will gain a knowledge of how to prevent disease, of how to choose scientific medical treatment, and of how to follow intelligently his physician's instructions, thereby shortening the process of disease and particularly relieving the mind from the worry inevitably associated with unanswered questions.

Reports on Chronic Rheumatic Diseases. Being the Annual Report of the British Committee on Chronic Rheumatic Diseases Appointed by The Royal College of Physicians. Number One edited by C. W. Buckley M.D. F.R.C.P. Cloth Price 12s 6d. Pp 159 with 8 illustrations. London H. K. Lewis & Co. Ltd 1935.

The stated object of the British committee in publishing this report is to bring to the notice of those interested in chronic rheumatism recent research work from the clinic and laboratory. By way of introduction, Copeman the secretary of the committee reviews the origin and work of the British committee, and Fisher discusses the merits of the classification of "rheumatic diseases" adopted by the committee and the reasons therefor, with a review of the pathologic changes seen in the more common types of chronic arthritis. The remainder of the book comprises eleven articles on various phases of the subject. Some of these articles are listed as "original" and express the author's ideas on certain subjects without reference to the literature. Others are essays on particular subjects, with brief reviews of new and old literature. A few confine themselves to a review of current literature on a given subject. Appended is a list of titles and references to about 300 articles relating to chronic rheumatism, which appeared in American, British and continental European literature between April 1934 and March 1935.

The most valuable parts of the report, which are well worth the price of the volume, are the article by Freeman, on the present position of allergy and hypersensitiveness in chronic rheumatism and arthritis, and that by Race on biochemical investigations in chronic rheumatic diseases. In any consideration of two such poorly defined states as allergy and "rheumatism" Freeman insists we must pick our way humbly and warily yet with courage. The author has done just that and has faced the situation frankly. Freeman's paper should be required introductory reading for any one daring glibly or critically to unite the terms 'allergy' and 'rheumatism'. In Race's excellent paper are discussed the significance of alterations in the sedimentation rate of erythrocytes in blood proteins, in pigments, in compounds of sulphur, in serum calcium and in serum magnesium studies on blood groups and remarks on the chemistry of urine and synovial fluid and on estimations of the metabolic rate in rheumatic diseases. Suggestions are made for future chemical investigations particularly on blood proteins. Miller reports preliminary observations indicating that some degree of hepatic impairment, as shown by tests of hepatic function, is present in about a third of the cases of rheumatoid arthritis, osteoarthritis, fibrositis, sciatica and gouty arthritis. The role of focal sepsis is briefly considered by Willcox. Buckley reviews the nervous manifestations of vertebral rheumatism and current ideas on the cause and treatment of ankylosing spondylitis. The possible relationship of tuberculous infections to Still's disease and rheumatoid arthritis, arguments on the acceptance of 'tuberculous rheumatism' as an entity, the influence of the thyroid and parathyroid glands, and the supposed rationale of their removal from rheumatic patients, the use of histamine in the treatment of myalgia and chronic rheumatism, and trends of research in this field during 1934 are additional subjects discussed (sometimes too briefly) by Moncrieff, Copeman, Fisher, Bach and Oriel.

The report is a helpful compilation of facts and ideas and is one with which students of the subject should become familiar.

It will serve as a useful supplement to the formal "statement of opinion" concerning the basic ideas of rheumatic diseases given by the Arthritis Committee of the British Medical Association and published in the *British Medical Journal* June 17, 1933 page 1041. The report of the British Committee on Chronic Rheumatic Diseases must face the criticism, however, that as a review of current literature (admittedly) it is not complete even in its presentation of recent British researches and its comments on those studies which are discussed in some detail are not sufficiently critical. To some the publication of such a report in book form may make it more available than if it was published in a national journal of fairly wide circulation and purchasable in reprint form later (as was, for example the recent first 'Rheumatism Review' of American and English literature published for the American Committee for the Study and Control of Rheumatic Diseases in the *Annals of Internal Medicine* this spring). Others may believe the latter method preferable in making the report, in the long run more widely available and incidentally less expensive for the reader. It is to be hoped that however presented, future reports will be forthcoming. They should be of decided value to every one concerned in the care of the innumerable victims of these diseases.

Healthful Living By Harold S. Diehl M.D. Professor of Preventive Medicine and Public Health the University of Minnesota. With an introduction by Morris Fishbein M.D. Editor *Journal of the American Medical Association*. Cloth Price \$2.50. Pp 354. New York & London: Whittlesey House McGraw-Hill Book Company Inc 1935.

As the first volume in a new series to be called the Whittlesey House Health Series, under the editorship of Dr. Morris Fishbein, the McGraw-Hill Company presents a book by Dr. Harold S. Diehl. Dr. Diehl has been for some time associated with the care of student health at the University of Minnesota and has also been secretary of the American Student Health Association. He has thus an excellent background for the development of a book of this type and he adds to this a power of clear and concise expression which is unusual among medical writers. After a discussion of the possibilities for improving health and lengthening life, he discusses mental health and the normal sex life, then he answers the usual questions relative to tea, coffee, tobacco and alcohol, exercise, fatigue, rest, fresh air and diet. These considerations occupy ten chapters. There follow chapters on specific disease prevention, the common cold, the care of the eyes, ears, nose, throat and teeth, a consideration of the glands, the care of the aged and finally a chapter on the choice of a physician. These excellent discussions are supplemented by a well chosen bibliography and an adequate index. The book is reasonably priced, well printed, beautifully bound and an excellent item for recommendation by any physician to a patient who wants a book on personal hygiene.

Trattato di anestesia. Narcosi—anestesi locali regionali spinali. Da A. M. Dogliotti docente di patologia chirurgica nella R. Università di Torino. Prefazione del Prof. Ottorino Uffreduzzi. Cloth Price 75 lire. Pp 552 with 253 illustrations. Turin: Unione Tipografica Editrice Torinese 1935.

The preface is written by Professor Uffreduzzi. In the first chapter there is a historical sketch concerning general and other anesthetics. In succeeding chapters the author covers the physiology and pathology that it is well for the anesthetist to consider in his work and also the various factors that bear on the production of anesthesia from all points of view. He describes the various signs and stages of anesthesia in a novel manner. He discusses regional anesthesia and the various types of injections, emphasizes respiratory difficulties attendant on these methods and shows how artificial respiration should be carried out. He discusses postoperative pulmonary complications and the use of carbon dioxide and oxygen in their prevention and treatment, and various other complications. He shows most of the types of apparatus for administration of general anesthetics that are used throughout the world. He discusses ether, chloroform, ethyl chloride, vinethene and nitrous oxide and presents charts showing signs of anesthesia with chloroform, nitrous oxide and ethylene. He takes up cyclopropane, acetylene, tribrom-ethanol and intravenous anesthesia, especially with *n*-methyl cyclohexenylmethylmalonylurea sodium. He also

discusses preliminary medication and basal anesthesia. He elaborates his own method of peridural anesthesia and discusses in great detail spinal anesthesia and the different methods of its production. For all those who read Italian, this is a valuable book.

Asylum By William Seabrook. Cloth. Price \$2. Pp 263. New York: Harcourt Brace & Company, 1935.

The name of this author is widely known because of his contributions to anthropology, ethnology and travel. Some time ago, feeling himself under the influence of alcoholic addiction, he voluntarily entered an institution for the mentally defective and submitted himself to retention, during which time he overcame completely the craving for alcoholic liquors and obtained an insight into modern methods of caring for the mentally sick. His book reads like a novel but is accurate and should be of great value in carrying to people generally a better idea of modern methods and a better understanding of those who suffer with mental diseases. Although published but a short time ago, the book has already passed through several editions and is listed among nonfiction best sellers. Every physician will find it a welcome addition to his correlated reading in medical work. There are occasional passages of a "blue" character, which may interfere with a general recommendation of the book to younger readers.

The Ordinary Difficulties of Everyday People By John Rathbone Oliver. Cloth. Price \$2.75. Pp 296. New York & London: Alfred A. Knopf, 1935.

Dr. Oliver is a combination of priest, physician, novelist and scholar. His writings have attracted more than ordinary attention in their special field. The present book is a series of philosophical comments on babies and children, poets and dramatists, school and the home. The author discusses youth, social ambitions, medical schools and a great many of the other aspects of modern life. There are chapters on compensations, on marriage, on the dangerous age and on old age. To all his comments the author brings a ripe wisdom and a wide experience of human life seen in the various capacities in which he has lived and worked. It is a book that repays careful reading and is sure to benefit many a troubled mind.

Around a World on Fire: Exploits and Escapes of an Austrian World War Surgeon By Karl E. Kassowitz. Cloth. Price \$2. Pp 198 with illustrations by Hans V. Schrötter. Milwaukee: The Author (Gutenberg Publ. Co.), 1935.

The experiences of physicians during the World War were probably as extraordinary and varied as those of any other group. The author of this volume, who is now a physician in Milwaukee, served as a front line surgeon with the Austrian army. After being captured, he did some work in Russia, going eventually to a prison camp in Siberia. With another physician he escaped in Chinese disguise and traveled across China, finally reaching Peiping. From there he came to the United States and from there he traveled back to Austria. He has a flare for what is dramatic and he tells his story with literary simplicity. Some extraordinary drawings have been contributed by Hans V. Schrötter.

The Stomach and Duodenum By George B. Eusterman, M.D., F.A.C.P., Head of Section in Division of Medicine, The Mayo Clinic, and Donald C. Balfour, M.B., M.D., LL.D., Head of Section in Division of Surgery, The Mayo Clinic and Members of the Staff, The Mayo Clinic and the Mayo Foundation for Medical Education and Research. Cloth. Price \$10. Pp 958 with 436 illustrations. Philadelphia & London: W. B. Saunders Company, 1935.

This splendid book covers all phases of diseases of the stomach and duodenum in a complete manner. Not only have Eusterman and Balfour stated the medical and surgical sides especially well but their colleagues at the Mayo Clinic have contributed a number of complete and up-to-date chapters on the physiology, pathology and roentgenology of this most important part of the gastro-intestinal tract. The newest methods and tests both for diagnosis and for treatment are clearly stated. A good bibliography is given with each chapter. The book contains much authoritative information and it is well balanced and concise. There are a large number of illustrations, which are unusually well done.

This book should serve not only as a textbook for the student and the general practitioner but also as a reference book for the internist and the surgeon.

Celsus De Medicina Volume I With an English translation by W. G. Spencer, M.S., F.R.C.S. In two volumes. Cloth. Price \$1.50. Pp 409. Cambridge, Massachusetts: Harvard University Press, London: William Heinemann Ltd., 1935.

It is well to have in one of the fine translations made available by the Loeb Classical Library this excellent translation of the contribution of Celsus. A brief introductory note outlines the most valuable features of the work and discusses the much debated question as to whether or not Celsus was a physician or merely a translator of an old Greek work on medicine. The conclusion of Dr. W. H. S. Jones, who writes the introduction, is to the effect that Celsus must certainly have had considerable medical experience. For all purposes that would have made him a doctor in early Rome.

Réactions labyrinthiques et équilibre latéral labyrinthique. Par G. G. J. Rademaker, professeur à l'université de Leyden. Préface du Professeur Georges Guillaumin. Papier. Price 80 francs. Pp 262, with 124 illustrations. Paris: Masson & Cie, 1935.

After a preface by Georges Guillaumin and some introductory remarks by the author, in which some of the historical aspects of labyrinthine reactions are discussed, Rademaker devotes his first chapter to the reactions produced by movements in a rectilinear plane. This is followed by a chapter on the various methods and types of labyrinthine stimulation in animals and man. The illustrations, which are numerous and illuminating, include photographs of movie films showing the body movements of experiments with animals, during falling and turning. The work is supplemented by a complete bibliography. The text is most readable, the subject is presented in a well organized and clear manner, and the work as a whole is a valuable addition to the literature on labyrinthine reactions. From both a scientific and a practical standpoint it should prove of great value to all otologists and to all others who are interested in the important investigation of the vestibular mechanism and knowledge concerning it.

Berättelse från styrelsen för cancerföreningen i Stockholm för verksamhetsåret 1934. Index of Papers Published at the Radiumhemmet 1909-1934. Report on Cases Treated at the Radiumhemmet 1921-1934. Paper. Pp 64. Stockholm: H. L. Beckmans Boktryckeri, 1935.

This report is divided into three parts. The first part, which is in Swedish, covers the activities of the cancer society in Stockholm in 1934. The second part lists the papers published by Radiumhemmet in the years 1909 to 1934. The third part gives a tabular summary of the cases treated at Radiumhemmet from 1921 to 1934. The report will interest all who are concerned actively with the control and treatment of cancer.

The Story of Medicine in the Middle Ages By David Riesman, M.D., Sc.D., Professor of the History of Medicine, University of Pennsylvania. Cloth. Price \$5. Pp 402 with 80 illustrations. New York: Paul B. Hoeber Inc., 1935.

This volume traces the rise of medicine and surgery from the time of the school of Salerno through the period of Paracelsus. Special chapters concern the development of the great universities, the work of the Arabian and the Jewish physicians, the rise of surgery, the great plagues and manias, the origins of syphilis, the textbooks of the period, and the hospitals. The volume concludes with a discussion of the public's attitude toward medicine of that period. The book is handsomely printed and well illustrated. It presents a selection from the vast amount of material now available of those facts and factors which should be of greatest interest to the physician of today and also provides the philosophical comments of the author, which are never without interest.

Clinical Atlas of Blood Diseases By A. Piney, M.D., M.R.C.P., Assistant Physician, St. Mary's Hospital for Women and Children, London, and Stanley Wyard, M.D., M.R.C.P., Physician, The Cancer Hospital, London. Third edition. Cloth. Price \$4. Pp 116 with 38 illustrations. Philadelphia: P. Blakiston's Son & Co. Inc., 1935.

The classification of blood as well as of various types is becoming constantly more and more complex and difficult. Few physicians can keep abreast of the new discoveries in relationship to the types of blood as well as the variations that occur in blood diseases. This atlas provides a series of excellent illustrations, which will serve for use on the laboratory table beside the microscope.

Medicolegal

Birth Control Sale of Contraceptives Regulated—A Wisconsin statute limits to pharmacists and physicians the right to sell drugs, medicines, mixtures, preparations, instruments, and articles and devices, used or intended to be used to procure miscarriages or to prevent pregnancy. Such articles may be sold or disposed of only to married persons. To prevent the evasion of this statute, it forbids the manufacture, purchase, rental, possession or control of any slot machine or other means designed and constructed so as to contain such articles and to release them on the deposit of a coin or other thing of value. Wis Stats, 1933, section 351.235.

The defendant, the proprietor of an oil station, permitted a vending machine to be placed in the mens wash-room on his premises, adapted for the vending of the forbidden articles or of some of them, although susceptible of use for vending lawful merchandise. The machine bore signs reading "Sold only for the prevention of disease" and "Minors are prohibited to operate this machine." Representatives of the police department deposited 10 cents in the machine and it delivered an article commonly used for contraceptive purposes. The defendant was convicted in the district court and in due process the case came before the Supreme Court of Wisconsin. The defendant contended that the act was so vague and indefinite as to be unconstitutional. Many articles with innocent and lawful uses were covered by it—for instance, many drugs, medicines, instruments and devices—simply because they were susceptible of use to prevent conception or to produce abortion. The act the defendant contended, could not be read by those affected by it with any fair chance of arriving at its precise meaning.

The act is not drafted with the precision that is desirable, said the Supreme Court, but the court must give effect to its intent, when that is clear, rather than to its letter. Its intent is to be gathered from the whole statute and not from words and phrases separated from their contexts. The act covers only drugs, medicines, mixtures, preparations, instruments, articles and devices that are "used or intended or represented to be used" to procure a miscarriage or for preventing pregnancy. It is not lightly to be assumed that the legislature intended the act to cover articles having legitimate common uses, simply because they are susceptible of use for improper purposes. The limiting words in the statute, "used or intended or represented to be used," are to be construed, in the opinion of the court, to mean (1) articles solely capable of use as contraceptives or abortifacients and (2) articles appropriate for use as contraceptives and abortifacients and sold with the intent or purpose that they be so used or with the representation that they are effective for that purpose.

Applying to the case the principle enunciated in *Youngs Rubber Corporation v C I Lee & Co* 45 F (2d) 103,¹ the court concluded that it was the intent of the legislature to deal in the statute under which prosecution was brought with articles whose sole purpose, or whose intended purpose or

represented function, is to produce abortion or to prevent pregnancy and that in general it was the intention of the legislature wholly to prohibit the sale of such articles to unmarried persons or by any one except a physician or pharmacist.

Defendants contention that the notices on the vending machine on his premises, "Sold only for the prevention of disease" and "Minors are prohibited to operate this machine" were conclusive as to the purpose for which sales were made was rejected by the court. The sale of the device that was sold in this case, said the court in a public toilet, by a mechanical vending machine, was a sufficient warrant for the inference that the purpose of its sale was contraception and not merely the prevention of disease.

The judgment of conviction by the court below was affirmed—*State v Arnold* (1935), 258 N W 843.

Workmen's Compensation Acts Apoplexy and Insanity Following Minor Injury of Hand—A workman, 55 years old injured his hand slightly, in the course of his employment. He had a stroke of apoplexy within a few days thereafter and another stroke a few months later. Subsequently he became insane. A claim for compensation was filed with the workmen's compensation bureau, which the bureau rejected. The court of common pleas however, reversed the bureau's order. Thereupon the employer appealed to the supreme court of New Jersey.

The claim for compensation was based on the theory that an embolus originated in the injury of the hand, was thrown off into the blood stream, passed through a persistent congenital opening between the arterial and venous sides of the heart [patent foramen ovale], and lodged in the brain instead of in the lungs, where it normally would have lodged but for the abnormal opening. Medical testimony conceded that this was a possibility, but it showed that the workman had arteriosclerosis, with involvement of the heart and kidneys, and that clinical examination failed to disclose a patent foramen ovale. When a man is 55 years of age, said the supreme court, and shows all the symptoms of arteriosclerosis, with involvement of the heart and kidneys, it is more reasonable to accept the hypothesis that the apoplexy was the natural result of the progress of arteriosclerosis than that it was due to an embolus, thrown off from a slight wound of the hand passing to the brain because of an alleged congenital defect, which occasionally occurs in children, who do not long survive, and is rare in adults. Compensation, continued the court, is not allowable for injuries caused by the natural progress of a disease from which a workman is suffering. Accordingly, the judgment of the lower court was reversed and compensation denied—*Hahne & Co v Guenther* (N J), 178 A 58.

Accident Insurance Death from Dislodgment of Kidney Stone an Accidental Death—The defendant insurance company promised to pay to the beneficiary of an insurance policy double indemnity if the insured died from external, violent and purely accidental means and not directly or indirectly as the result of disease or physical infirmity. After a fall as he was getting out of his automobile, the insured had a bruised spot over one kidney, and thereafter he suffered 'the excruciating pain which usually accompanies the presence of a kidney stone in the ureter.' A kidney stone, according to the report, obstructed the ureter, causing hydronephritis, which was followed by pyonephritis and then by hypostatic pneumonia, which caused death. The insurer refused to pay double indemnity and the beneficiary brought suit. The trial court took the view that physical infirmity contributed to the death and directed a verdict for the insurer. The beneficiary appealed to the Supreme Court of Minnesota.

The stone that caused death measured 1.5 by 6 by 6 cm (one half by 2½ by 2½ inches) and had "certain prongs or projections" which in the opinion of the plaintiff's doctors, were likely to prevent its dislodgment from the part of the kidney in which it was being formed unless there was an abnormal abdominal pressure, such as the blow which the insured received when he fell. They regarded the stone as harmless to the health of the insured except as it might be dislodged and pass into the ureter. Before the accident the insured apparently was in the best of health and all medical witnesses agreed that if there had been no kidney stone the fall would not have killed him.

¹ In this case the United States Court of Appeals Second Circuit in construing phraseology similar to that now under consideration in federal statutes relating to the transportation of contraceptives and abortifacients in the United States mail or in interstate commerce in any manner whatever said: Taken literally this language would seem to forbid the transportation by mail or common carriage of anything adapted in the sense of being suitable or fitted for preventing conception or for any indecent or immoral purpose even though the article might also be capable of legitimate uses and the sender in good faith supposed that it would be used only legitimately. Such a construction would prevent mailing to or by a physician of any drug or mechanical device adapted for contraceptive or abortifacient uses although the physician desired to use or to prescribe it for proper medical purposes. The intention to prevent a proper medical use of drugs or other articles merely because they are capable of illegal uses is not lightly to be ascribed to Congress. Section 334 forbids also the mailing of obscene books and writings yet it has never been thought to bar from the mails medical writings sent to or by physicians for proper purposes though of a character which would render them highly indecent if sent broadcast to all classes of persons. See *United States v Chesman* 19 F 497 498 (C C E D Mo.) *United States v Clarke* 38 F 500 502 (D C E D Mo.) *United States v Smith* 45 F 476 478 (D C E D W.) *United States v Dennett* 39 F (2d) 564 568 (C C A 2). It would seem reasonable to give the word adapted a more limited meaning than that above suggested and to construe the whole phrase designed adapted or intended as requiring an intent on the part of the sender that the article mailed or shipped by common carrier be used for illegal contraception or abortion or for indecent or immoral purposes. See *Bour v United States* 229 F 960 963 (C C A 7). However we do not find it necessary to decide this question in the present case. *Youngs Rubber Corporation v C I Lee & Co* 45 F (2d) 103.

The issue of the case on appeal turned on the answers to two questions. Is death, caused by the lodgment in the ureter of a kidney stone which a fall has dislodged from the kidney, "accidental" within the meaning of the policy? If so, is such death caused by external, violent and purely accidental means, and not caused directly or indirectly by disease or physical infirmity? Although the trial court took the view that physical infirmity contributed directly or indirectly to death, the Supreme Court was more cautious. It cited *Silverstein v Metropolitan Life Insurance Company*, 254 N Y 81, 171 N E 914, in support of the postulate that "when the abnormality was so remote in its potential mischief that common speech would call it not disease or infirmity but at most a predisposing tendency, the fact that it started and was made operative by violence so that death resulted did not prevent the violence from being considered the sole cause of the death." The Supreme Court professed to have no difficulty distinguishing between the present case and cases in which the insured was suffering from chronic disease, such as diabetes or nephritis, which impairs the health and weakens the resistance so that when aggravated by violence the disease causes death. The difference, said the court, lies in that in one case the disease is merely aggravated by the violence, while in the other it is in its fatal aspects entirely set in motion by the violence. Applying this rule to the case before it, the court concluded that the jury might justly find that violence was the sole cause of death. For that reason, the Supreme Court reversed the judgment of the court below and remanded the case for a new trial—*Mair v Equitable Life Assur Soc of United States (Munn)*, 259 N Y 60.

Malpractice Operation Without Consent Implies Injury, Scope of Lawful Malpractice Defense by Medical Society—The defendant, a physician, removed several moles from the face of a minor child. The patient's mother, acting as guardian, alleged that her child had been disfigured by the treatment and sued the defendant. She alleged, among other things, that the treatment given by the defendant was given without her consent or consent of her daughter, the patient. Judgment was given against her and she appealed to the Supreme Court of Errors of Connecticut.

The instructions given to the jury by the trial court were such as might have led the jury to believe that the plaintiff was not entitled to damages unless she proved not only that the defendant treated his patient without consent but also that his patient was in fact injured by his treatment. This, said the Supreme Court of Errors, was incorrect. The removal of the moles, if done without consent, was a trespass and had the legal effect of an assault, and an assault, even without specific proof of injury from it, entitles the plaintiff to at least nominal damages. "Every human being of adult years and sound mind has a right to determine what shall be done with his own body, and a surgeon who performs an operation without his patient's consent commits an assault, for which he is liable in damages." *Schloendorff v New York Hospital*, 211 N Y 125, 105 N E 92. But the erroneous instruction given by the trial court could have had no adverse effect further than to cause the plaintiff to lose a verdict for nominal damages and costs, and errors of such limited effect do not ordinarily warrant the reversal of a judgment.

Dr Standish was called as a witness for the plaintiff. After counsel for the plaintiff had examined him and after the witness had been cross-examined, the plaintiff sought on redirect examination to show that he was not disinterested. Counsel for the plaintiff proposed to introduce evidence to show that this witness, Dr Standish, and the defendant were fellow members of the Hartford Hospital Society, that both of them practiced as specialists in the same field, that the plaintiff's witness had without compensation treated the patient on whom the defendant had operated, for several months, trying to remove the scars attributed to the defendant's treatment, and that such services were rendered gratuitously, pursuant to an agreement among the members of the hospital society to render free treatment to a patient of a fellow member if that member was sued under circumstances such as were present in this case, that the hospital society had a committee charged with the duty of determining whether, in any given case, there had been

malpractice, and that, in consideration of lowered premiums paid by each member, a blanket policy of insurance was issued to the members of the society. The trial court, however, refused the proffer of the plaintiff's counsel of evidence to prove these things. Counsel for the plaintiff asked a physician whom he had summoned as a witness whether he had not been told by telephone, by a physician on the staff of the New Britain Hospital, that he would be "run out of town" if he testified against the defendant, but the court excluded this testimony.

Counsel, said the Supreme Court of Errors, after he has called a witness and sought the benefit of his testimony, may contradict him by another witness, but he cannot directly impeach him unless it is shown to the satisfaction of the court that the testimony of his witness has taken counsel by surprise or is inconsistent with other statements made by the witness. Counsel must before he undertakes to impeach his own witness out of his own mouth, show that the witness is adverse or hostile, or show some equally potent reason, as the interests of justice under the circumstances of the case seem to the court to require. The Supreme Court of Errors, however, was unable to find anything in the record in this case suggestive of hostility on the part of the plaintiff's witness, Dr Standish, or of any unwillingness on his part to answer questions put to him, or anything else to justify an exception to the general rule regarding the impeachment of witnesses.

Counsel for the plaintiff was seeking by the questions asked of his witness, Dr Standish, and by the testimony that he proffered, to show that the medical society of which Dr Standish was a member had endeavored to use its influence to prevent the plaintiff from securing expert medical testimony in support of her claim. There can be no question, said the court, of the right of the society to investigate any claim of malpractice brought against any one of its members or to render such member any proper aid in his defense. The limits of such proper aid, however, manifestly do not include the production of testimony which is untrue or of opinions of witnesses which are not honestly entertained by them, or the prevention of the attendance of witnesses, or the suppression of any relevant evidence, or any other interference with the orderly and normal course of court procedure. Any act of such improper character by any member of the society, or participation in it by him, would render such member liable to statutory penalties and, it might be, for conspiracy at common law.

The Supreme Court of Errors found no reversible error in the rulings of the trial court—*Schmeltz v Tracy (Conn.)*, 177 A 520.

Current Medical Literature

AMERICAN

The Association library lends periodicals to Fellows of the Association and to individual subscribers to *THE JOURNAL* in continental United States and Canada for a period of three days. Periodicals are available from 1925 to date. Requests for issues of earlier date cannot be filled. Requests should be accompanied by stamps to cover postage (6 cents if one and 12 cents if two periodicals are requested). Periodicals published by the American Medical Association are not available for lending but may be supplied on purchase order. Reprints as a rule are the property of authors and can be obtained for permanent possession only from them.

Titles marked with an asterisk (*) are abstracted below.

Breeding Behavior and Tumor Incidence of an Inbred Albino Strain of Mice. J. J. Bittner. Bar Harbor, Maine—p. 113.
Glycolysis of Various Substrates by Extracts of Sarcoma and of Muscle. F. H. Scharles, M. D. Baker and W. T. Salter. Boston—p. 122.
Tumors of Digestive Tract. C. F. Geschickter. Baltimore—p. 130.

Treatment of Tumors and Effect of Disturbances in Fluid Exchange.—In experiments on fluid exchange, Shear employed a variety of substances and procedures in empirical attempt to alter the water content of tumor cells or to damage them by excessive intake of fluid or by excessive loss of fluid from the tumor. No hemorrhagic reaction was noted with histamine, but two tumors (sarcoma 180) receded and the slight retardation that occurred in the growth of the treated tumors may have been due to the treatment. The results with peptone were negative. In the mice treated with agar, one tumor receded completely and several tumors retrogressed. In the experiments with pneumococcus antibody and pneumococcus soluble specific carbohydrate, hemorrhages were observed in several of the tumors but no clear cut effect on tumor growth was obvious. In tumor-bearing mice complete withdrawal of drinking water resulted in earlier death than in non tumor-bearing control mice. Massive bleeding did not have a pronounced effect on tumor growth, although it seemed in some experiments to result in smaller tumors, this may well have been due to the general poor condition of the mice and not to a specific effect on the tumors. The various diuretics employed did not seem to influence the growth of the tumors. With acacia, recession of the tumor occurred in a few instances in a few other instances, liquefaction occurred apparently as a result of the treatment. With egg albumin and with serum albumin, a retarding influence was noted in a few instances. In one experiment with horse serum hemorrhage or striking destruction of the interior of the tumor was obtained in twelve out of seventeen mice, in some cases the tumor grew again but in three mice there was complete recession. With sublethal doses of meningococcus filtrate, hemorrhages were obtained in the tumors. Many of the mice died but in the survivors some tumors receded and grew again while others receded completely. Sodium oleate also produced hemorrhage or liquefaction in an apparently significant number of cases.

Island Cell Adenomas of Pancreas Cultivated in Vitro.—Murray and Bradley cultivated in vitro two adenomas of the islands of Langerhans from two human adults for periods of five weeks and six and one-half weeks respectively. The vitality of the explants was undiminished at the end of these periods. The two series of cultures from the two tumors differed from each other in much the same degree as the tumors differed in morphology. The behavior of the cultures from these pre-

sumably benign tumors was less irregular than the behavior of cultures of normal young and embryonic animal pancreas as reported by other workers. March 19, 1935, six cultures of one of the tumors were inserted into the axilla of a diabetic member of the staff who had volunteered to receive them. She had been maintained in normal health and activity over a period of twelve years by the injection of 20 units of insulin twice a day. Previous to the grafting the cultures had been grown for three weeks in the recipient's plasma, and the grafting procedure followed in general the technic of Stone, Owings and Gey for parathyroid transplantation through tissue culture. At the time of the last passage of each explant the medium from which the culture was cut was plated on blood agar for additional assurance that it was bacteriologically sterile. Since the transplantation the patient has been kept on a regimen of 18 units twice a day, and weekly tests of her blood sugar and urine sugar have been made. On June 12 no significant change in the level of blood or urine sugar had been registered.

Sensitivity of Wassermann Antigens in Relation to Rate of Dilution. A. J. Casselman, Camden, N. J.—p. 443.

Decidual Hyperplasia of Endometrium in Absence of Pregnancy.—Reinhart gives the histologic pattern and history that suggested the diagnosis of "decidua menstrualis" in a non-pregnant patient. Comparison of this case with three others in which diffuse decidual hyperplasia was present, one with chorionic villi and two without demonstrable villi giving clinical histories suggestive of early abortion, indicate a common etiology. The principal symptom of the present case was the periodically recurring, profuse, prolonged, white discharge with very little blood. Histologic examination presented little evidence of the mechanism by which the discharge was produced. However, the uterus was removed at a time during which there was clinically little discharge present. Whether this discharge was the result of the involution of the corpus luteum or of local inadequate nutrition associated with the rapid tissue growth has not been determined. If the involution of the corpus luteum is the mechanism by which this discharge is brought about, the diagnosis of "decidua menstrualis" might be competent. Histologic examination of hyperplastic decidual tissue removed in the three cases cited, during the discharge, presents a similarity to the early phase of menstruation.

Microscopic Observations in Congenital Encephalitis.—Amolsch investigated the etiologic and pathologic features of the brains of forty-six cases of incomplete cerebral development that exhibited in some degree the cellular features of encephalitis. The brains, ranging in fetal developmental age from 12 weeks to term were subjected to uniform cross-sectioning throughout the entire ventricular system. None of these infants survived longer than forty-eight hours after birth. Every brain in the series exhibited some degree of subependymal cellular activity. The degree of activity was proportional to the degree of hypodevelopment. The nature of the reaction was in no manner different in location, extent or cellular character from that seen in cases interpreted as congenital encephalitis. Subependymal infiltration of small round cells and perivascular mantles of such cells, found in the brain of the new-born, are not to be interpreted as an expression of inflam-

mation It is definitely developmental in nature This reaction is most pronounced in the prematurely born infants Between the twelfth and the twenty-eighth week of fetal development this reaction forms a prominent mass over the basal ganglion beneath the lateral ventricle The most prominent exhibit of the incomplete state of cerebral development in the term or near term infant is observed in the angle between the caudate nucleus and the thalamus and at the upper lateral angle of the lateral ventricle in sections through the anterior half of the brain Incomplete cerebral development at birth offers a distinct liability to cerebral and ventricular hemorrhage during birth and to late hypodevelopment, gliosis and possible gliomatous tumor formation in later life Congenital encephalitis by itself can exist, but such a diagnosis must depend on the presence of a true inflammatory reaction, cellular changes associated with development must be excluded from the criteria supporting such a diagnosis

Pathologic Changes Resulting from Accurately Controlled Artificial Fever—The study of Hartman and Major on the pathologic changes resulting from artificial fever therapy consist of two clinical cases coming to necropsy after fever therapy and of twenty dogs, eighteen of which were subjected to fever of various durations and degrees and two of which were used as controls, being given excessive amounts of sodium amytal, a sedative used in all but two of the other experiments and in the human cases They found that the pathologic changes in the human cases and the experimental animals were engorgement of the blood vessels, especially the capillaries, hemorrhage and degeneration The most vital changes seen were those in the brain, amounting to hemorrhagic encephalitis in some instances, those in the lung constituting hemorrhagic pneumonia and those in the adrenal characterized by degeneration in the cortex with hemorrhage Death occurring during or immediately after treatment was due to vascular collapse Although the changes described have been noted in animals receiving morphine alone as a sedative, the human patients and most of the animals received sodium amytal, a drug which in large amounts is known to produce congestion and even capillary damage, especially in the brain Since fever therapy and sodium amytal tend to produce marked dilatation and engorgement of blood vessels, the authors suggest that the combination should not be used in patients

Bleeding Gastric and Duodenal Ulcers D P MacGuire New York.—p 431

Histidine in Treatment of Peptic Ulcer—Eads treated thirty-five cases of peptic ulcer with intramuscular injections of a 4 per cent solution of histidine hydrochloride, averaging twenty-four injections with no local or systemic reaction Six patients, three with gastric ulcers and three with duodenal ulcers in which the average history of symptoms was two and one-half years, showed immediate clinical and roentgen evidence of cure. Symptomatic relief of distressing complaints was usually evident after the first three or four injections The gain in weight was the most marked. None of these patients were restricted as to diet or placed on medication. None of them, after a period of observation of six months or more, have shown any recurrence. Five showed some decline in the acid curve, but not to normal figures Eight patients presented definite clinical and roentgen improvement, not so rapidly as the first group, but still definite

There were six duodenal ulcers and two gastric ulcers in this group Six patients showed a gain in weight Five began to show improvement after the tenth injection, two after the fifteenth and the remaining one after the twenty third injection. Five were on no dietary restrictions, three were advised regarding elimination of tobacco, coffee, alcohol and so on, and one had alkalis at times, but not regularly The average duration of symptoms in the group was four and one half years. Nine patients showed some clinical improvement but no roentgen change The symptomatic improvement was much slower than it was in the other two groups, and not until eighteen or more injections had been given was any improvement noted. These were all duodenal ulcers with an average history of six years. There were some dietary restrictions imposed in three cases with little or no medication given. Twelve patients were unimproved after the completion of twenty four injections. Three of these were given further injections—two were given thirty injections and one thirty-six with no improvement noted. At times experiments were made with a fairly rigid dietary schedule and alkalis were given in seven cases with no appreciable change in the symptoms. Seven of this group were classified as obstructive lesions of a varying degree and were not improved at all In three of these the symptoms appeared aggravated by the injections and four showed a loss of weight. Operations were subsequently performed in three of the obstructive cases with one fatality due to pulmonary infarct. Of these twelve patients showing no immediate improvement, three subsequently appeared to show definite improvement a week or so after the completion of injections, after being placed on a strict orthodox medical regimen, when before the injections such a treatment had been of no value. This suggests the possibility of some delayed benefit. The duration of symptoms in this group was the longest. These were for the most part ulcers that are resistant to treatment and were complicated by some obstructive phenomena in seven cases

Anomalies of Circle of Willis—Saphir states that anomalies of the circle of Willis, with resulting interruption of the circulation between the internal carotid and vertebral arteries may form the anatomic basis of cerebral vascular disturbances. The recognition of such anomalies aids in the explanation of cerebral hemorrhage and encephalomalacia on morphologically demonstrable grounds in the absence of occluding lesions of the supplying arteries. In addition to local causes for encephalomalacia and cerebral hemorrhage the condition of the myocardium and evidence of myocardial failure in the various organs should be considered. Three brains are described which revealed anomalies of the circle of Willis involving the posterior communicating arteries, and an abnormal origin of the posterior cerebral artery in one case. Two of these brains revealed areas of encephalomalacia and cerebral hemorrhage, without the presence of occluding lesions in the supplying arteries. Whereas the posterior communicating arteries are not essential in the maintenance of the circulation of the brain under normal conditions, a free unhampered collateral anastomosis between the internal carotid and vertebral arteries is important in instances of diffuse arteriosclerosis of the arteries of the base of the brain combined with beginning myocardial failure. This conception of the origin of these brain lesions is based on morphologically demonstrable changes and does not require the assumption of theoretical functional disturbances of the circulation

- Provisions for Schooling of Blind and Partially Blind E M Van Cleave New York—p 473

Tobacco-Alcohol Amblyopia—Carroll studied fifty-five cases of toxic amblyopia associated with the use of tobacco and alcohol He feels that the diagnosis could be made earlier and more often if studies with the tangent screen were performed more frequently The condition should not be confused with early senile macular degeneration The amblyopia may

develop after the use of only moderate quantities of tobacco and alcohol, and these substances should be considered as only two factors that when combined with others, bring about the disease Extensive medical, neurologic, dental and otologic examinations were carried out on the patients, and the results are presented The progress of the disease was followed by numerous ophthalmic re-examinations over a period of many months and the relation of abstinence to improvement was especially noted The value of abstinence is stressed but cases are cited in which the patients improved without markedly decreasing their use of tobacco and alcohol There is great variability in the normal course of the disease, and this should be considered in attempting to evaluate the effect of any treatment

Cervical Sympathectomy in Retinitis Pigmentosa—De Takáts and Gifford performed sympathetic denervation of the eye to improve the visual acuity and visual fields of six patients suffering from retinitis pigmentosa Of eleven operations four consisted of cervicodorsal and seven of superior cervical ganglionectomies The latter, particularly if combined with a stripping of the internal carotid artery, seems to be the simplest and most constantly reliable method of obtaining complete sympathetic denervation The test of complete sympathetic denervation was the failure of cocaine to dilate the contracted pupil Not one of these patients showed an increase in visual acuity or in the visual fields One younger patient reported an improvement in night blindness None of them showed progress of the disease, but the longest period of observation was only a year and a half The only possible benefit of sympathectomy on dark adaptation and minimal light perception in these patients seems to be that which might arise from halting the progress of the disease A later report will be necessary to recommend or condemn the procedure definitely

Fascial Sarcoma—Ewing points out that the term fascial sarcoma should be restricted to the fibromas, fibrosarcomas, fibrochondromas or parosteal osteosarcomas originally described and designated as fascial sarcoma by Virchow It should not be employed for intermuscular myxosarcomas The intermuscular myxosarcoma, often called fascial sarcoma, is probably derived from fat lobules and presents the structure of embryonal mucous tissue or embryonal fat tissue It is rarely, if ever, of traumatic origin and is often radiosensitive The common liposarcoma of the trunk and limbs is derived from adult fat tissue and presents the structure of large granular cells, such as those seen in chronic inflammation of fat tissue The structure varies greatly with the degree of malignancy It seems to be occasionally of traumatic origin. The degree of radiosensitivity of the primary tumor is uncertain, but the recurrent

tumors are radioresistant. It appears that two types of liposarcoma may be recognized, one the myxoliposarcoma of embryonal structure and the other the granular cell liposarcoma of the adult type. Liposarcoma of both types is comparatively common in the region of the hip, knee, shoulder and trunk. It runs a characteristic clinical course, usually recurring after operation and proving fatal from infection, sepsis and metastases to the lungs. Since some are radiosensitive, it is recommended that all bulky tumors of the soft parts be submitted to treatment with high voltage radiation before surgical intervention is resorted to.

Changes Produced in Carcinoma of Cervix by Roentgen Irradiation—Arneson and Stewart call attention to the necessity of delivering a larger dose of external radiation to the parametrium if any advance is to be made in the cure of cervical carcinoma. The treatment recommended consists in increasing the target skin distance for external irradiation from 50 to 70 cm, using multiple portals (from four to six) and delivering at least 2,000 roentgens to each field within a period of about three weeks. This method delivers approximately from 3 to 3.2 threshold erythema doses to the cervix and somewhat less to the parametrium if four portals are used, and slightly more if six portals are employed. The percentage of satisfactory clinical regressions parallels the increase in the doses. The microscopic regressions tend to parallel the clinical regressions. Polypoid lesions show the greatest clinical regression with external irradiation. Crateriform lesions appear the least susceptible. The latter usually constitute a more advanced clinical type of disease. Local cure from external irradiation is exceptional with the doses used. Complete temporary epithelialization of the primary lesion is not uncommon. Despite successive biopsies showing progressive degeneration of the tumor and occasionally complete disappearance of disease in one or more specimens examined at the end of the period of external irradiation, the tumor tends almost inevitably to reappear in a histologic form that is apt to resemble closely the initial tumor. Hence restraint of growth is but a transient phenomenon. For this reason the authors have little hope that the methods described will control more than a minor percentage of tumors with parametrial extensions. It is thought, however, that the dose to the parametrium may be increased.

Acute Abdominal Pain in Sickle Cell Anemia—Campbell enumerates the abdominal symptoms and signs most commonly found in sickle cell anemia and reports six cases in which the abdominal manifestations were conspicuous. Many patients with the active form of the disease at times have attacks of acute abdominal pain, fever, mild jaundice and leukocytosis. The pain may be in the left upper quadrant, suggesting splenic infarcts, or in the epigastrium and right upper quadrant, simulating cholecystitis or hepatic tenderness from other causes or even gastric or duodenal disease. Again, there may be a cramplike pain, either generalized or localized in the epigastrium, associated with nausea, vomiting, obstipation and distention and strongly suggesting intestinal obstruction. Instances are known in which acute appendicitis has been mimicked, and on occasions acute salpingitis has been erroneously diagnosed. The symptoms and signs may vary in the same person from day to day, so that more than one abdominal condition is portrayed. The establishment of the presence of sickle cell anemia and the decision that the abdominal symptoms are or are not attributable to this disease are the two obvious steps in the diagnosis. Leukocytosis is usually present in the abdominal crises of sickle cell anemia and is often much higher than that which would be expected of the simulated disease. Jaundice due simply to uncomplicated sickle cell anemia is not obstructive, hyperbilirubinemia, hyperurobilinuria and usually an indirect van den Bergh reaction and urobilin in the highly colored stools are present. The most widely accepted theory is that pain is due to infarcts in the spleen or to the perisplenitis so frequently observed at necropsy. These could account for many of the symptoms, particularly the pain in the left upper quadrant and epigastrium and perhaps the tympanites. They do not so readily explain the pain and tenderness in the right upper quadrant and over McBurney's point or that in the lower part of the abdomen. Enlargement of the liver may in some way be responsible for the hypochondriac pain on the right side, but this is not likely. There is no specific therapy for the disease or for the abdominal

crises. General supportive measures, hygienic improvements and transfusions, if the hemoglobin concentration is very low, are customarily employed for the disease itself. For the abdominal manifestations a policy of watchful waiting with mild sedatives, heat and enemas is all that seems advisable. Patients with this disease not seldom become candidates for some form of operative therapy unconnected with the anemia. Patients with the latent form stand such procedures as well as other people, but patients in whom the disease is or has been in active phase may occasionally do very badly.

Experimental Staphylococcal Arthritis and Bacteriophage—Inge and Toumey tested the efficacy of bacteriophage therapy in infections of the joints under controlled conditions in six series of dogs (from four to sixteen). 1 Suppurative arthritis of the knee was produced and left untreated to determine the course of the disease. 2 The effect of repeated injections of bacteriophage alone and of broth alone were studied. 3 Purulent arthritis was produced in both knees with subsequent repeated injections of bacteriophage into the left knee, the right remaining as a control. 4 Bacteria suspended in broth were injected into the right knee, and into the left knee the same dose of bacteria suspended in bacteriophage was injected, no subsequent bacteriophage treatments were given. 5 Dogs were treated as in series 4, but with a more potent bacteriophage. 6 A bacteria-bacteriophage mixture incubated for varying lengths of time before the injections were made was injected into the left knee, while bacteria alone were injected into the right knee as a control. The experiments establish the following facts: 1 Acute suppurative arthritis can be produced in the dog's knee with the staphylococcus, the lesion showing a tendency to subside spontaneously and the duration of the infection varying in different dogs. 2 Repeated injections of bacteriophage alone into the knee joint of a normal dog are not without some danger of the formation of mild acute synovitis. 3 Repeated injections of broth alone into the normal knee cause no such arthritis. 4 Bacteriophage is useless as the sole means of protecting a joint against a closed suppurative arthritis. 5 The failure of bacteriophage to act in such a situation is due to complicated biologic reactions not elucidated by this series of experiments but probably in great part related to the inactivation of bacteriophage by body fluids. 6 The presence of serum "antiphage" does not exert any deleterious influence on the outcome of such experiments.

Iron Requirement of Normal Adult—Farrar and Goldhamer observed a healthy man, aged 26, who carried on his usual duties as a graduate student for 316 days on a diet with an average daily iron content of 4.9 mg. During the last thirty-one days of this period the subject was in iron balance when the diet contained 5.2 mg of iron daily. The blood hemoglobin, blood iron and red blood cell levels were within normal limits. Two other male subjects were likewise in iron balance after four and five months on diets containing 7.1 and 7.8 mg of iron daily, respectively, and their blood contained normal amounts of hemoglobin and red blood cells. A young woman living for more than a month on a diet containing 9.1 mg of iron daily was in iron balance during the intermenstrual phase. The total menstrual blood loss represented 33 cc. of the sub-

ject's blood Normal urinary iron amounts to about 0.02 mg per hundred cubic centimeters of urine. These observations, together with those in the previous literature indicate that the iron requirement of the normal adult male is not more than 5 mg daily.

Food Poisoning in Hospitals—Matz stresses the fact that insistence on personal cleanliness of the employees of the dietetic department of hospitals and domiciliary institutions is an insurance against outbreaks of food poisoning. It is essential that food handlers be instructed to scrub their hands with soap and water prior to the preparation of meals or the handling of food. As a means of preventing outbreaks all food handlers should be examined periodically to ascertain whether or not they are carriers of the bacteria that are commonly found in cases of food poisoning. Employees found to be such carriers should be promptly transferred from the dietetic department. The elimination of rodents, vermin and flies from the kitchens and dining rooms will prevent food poisoning, as they are carriers of bacteria, commonly the cause of such outbreaks. Insufficient refrigeration of cooked or uncooked foods is a frequent cause of food decomposition and outbreaks of food poisoning. Cooked or uncooked foods, as well as pastries, should not be left uncovered and at room temperature, thus inviting bacterial contamination and bacterial growth. The principal *Salmonella* group of organisms found in cases of outbreaks of food poisoning are *Salmonella aertrycke* (*Bacillus paratyphosus B*) of animal origin, *Salmonella enteritidis* of Gartner and *Salmonella cholerae-suis*. In addition the staphylococcus streptococcus and *Clostridium botulinum* are frequent bacterial contaminants of foods. All these organisms are capable of generating toxins that may contribute to the symptoms which usually accompany outbreaks of food poisoning. A review of the four outbreaks recorded by the author indicates that the principal factor responsible for the poisoning was insufficient refrigeration of various foods. There is a possibility that one outbreak was caused by staphylococci, which were found under the fingernails of food handlers.

Bitterling Pregnancy Test—Owen and Cope were unable to confirm the results of the bitterling pregnancy test reported by Kanter, Bauer and Klawans. Strongly positive results were obtained with seven out of twenty fish tested with specimens from nonpregnant women. These false positives occurred chiefly in premenstrual and postmenstrual specimens. Interval specimens were usually negative. False positive results were obtained with five out of sixteen fish tested with male urines.

Arsenic in Human Tissues and in Tobacco—Boos and Werby find that all hair contains arsenic, that is to say, arsenic determinable by ordinary forensic analysis. This arsenic is being constantly excreted by the hair, which constitutes an important organ of elimination for this poison, but the expulsion of arsenic by hair is a comparatively slow process at any time. The arsenic is taken up by the roots of the hair, where it is fixed and, as the hair grows, any of the metal that has been absorbed grows out with it. They believe that the only logical answer to the increased amount of arsenic in the hair is that the food which we eat today contains more arsenic than was formerly present in food. Remington has noted that the arsenic of the body is usually attributable to food, because of (1) chemical treatment in manufacture, (2) absorption by plants from the soil, (3) presence in sea food and (4) the widespread use of arsenical sprays in America. Headden found that our virgin soils contain from two and one half to five parts per million of arsenic and the underlying marl from four to fifteen parts, and that the crops grown on such soils, and the animals fed on these crops contain arsenic. The arsenic content of American cod liver oils offers some startling information. Holmes and Remington in their examination of twenty samples, comprising six geographic types, found very high amounts of arsenic. The average arsenic content of the oils is calculated to the trioxide and was found from 18 to 44 parts per million. The examination of human bone in poisoning cases showed that, when the individual lived only a few hours, the amount in the bone was quite small, whereas the bone of patients who had lived several days showed a substantial quantity of arsenic. A study of the bones of food animals, purchased at a market, showed quite high figures, particularly the bones of beef cattle. Two popular pipe tobaccos and two well known cigaret tobaccos were examined and it was found that tobacco (pipe) A contained 133 tobacco (pipe) B 95, tobacco (cigaret) C 11 and tobacco (cigaret) D 9 parts of arsenic per million.

Effects of Long Continued Basic and Acid Diet—Over a period of approximately six weeks Doane studied the effect of basic diets on the acid-base regulatory mechanism, gastric acidity and chemical change of patients with arthritis hyperacidity and gastric ulcer. With diets predominatingly basic to a high degree, urine pH rose with maximal effects in some cases after the third week. The plasma carbon dioxide combining power and the blood pH resisted any change except to a minor degree. Gastric acidity was reduced in one patient but little or not at all in the other patients. Clinical improvement was particularly noted in one patient with arthritis characterized by lessened joint pain and beneficial effect on constipation and other intestinal symptoms. The effect of diets high in excess acid ash were studied on patients with achlorhydria and achylia including a group of five patients with pernicious anemia. In one patient with arthritis and achlorhydria there was a definite return of free hydrochloric acid. No definite change was noted in other cases of achlorhydria or achylia with pernicious anemia. Though consistently acid urines were obtained on this diet no constant change in blood pH was noted. An occasional lowering of the plasma carbon dioxide combining power was noted with no change in the blood pH , an indication of moderate compensated acidosis. The use of foods high in excess acid ash and iron is recommended for cases of hypochromic anemia with achlorhydria. A control group of patients receiving alternating basic and acid meals was observed. Though basic ash tended to exceed acid ash in these patients, little change in urine, blood or gastric reaction could be observed. These observations substantiated the thought that consistently high basic or acid diets for prolonged periods are necessary before demonstrable changes are to be expected. The separation of the ingestion of basic and acid foods from meal to meal has no scientific basis to support it as a therapeutic measure dependent on restoration and maintenance of the acid base equilibrium of the body.

 *Unusual Allergic Property of Autolyzed and Decomposed Proteins O H Brown Phoenix Ariz.—p 314

Unusual Allergic Property of Autolyzed and Decomposed Proteins—Brown states that autolyzed, fermented or decomposed proteins are more prone to act as allergens than

are fresh, unchanged proteins or normally digested proteins. Fresh foods may undergo spoiling in the alimentary canal before they have had a chance to undergo normal peristalsis. It would seem that in certain cases a mild intestinal stimulant taken with food may prevent allergic reactions by stimulating peristalsis, mixing food and alimentary canal secretions, allowing normal digestion and inhibiting bacterial putrefaction. Green fruits and vegetables as ordinarily obtained have had hours of exposure to temperatures that promote chemical change. Canned fruits and vegetables are probably generally taken with more or less dispatch from the picking to the cannery, where little time is supposedly lost in getting them into the can. This may be an argument for canned over fresh fruits and vegetables—unless they really are fresh. The long time that cereals are kept before they are consumed may have something to do toward promoting sensitizations to them.

Sclerosing Solution in Treatment of Sinuses—Sherwood states that in 1933 Cutler and Zollinger called his attention to the use of sclerosing solution in the treatment of cysts and fistulas. During his work in the empyema service in the government hospitals during the World War he used 20 per cent bismuth and cottonseed oil in empyema cavities and branchial fistulas to outline the cavities and the fistulas. He found that in practically every instance of chronic empyema the bacterial count was rapidly lowered by these injections, even more so than with the use of standardized surgical solution of chlorinated soda. He also found that a number of branchial fistulas healed rapidly in some instances and slowly in others from the bismuth and cottonseed oil injections. Since then he has tried this in other sinuses and fistulas about the body with surprisingly good results. Two of the cases that he reports, in which the repeated injections of bismuth had failed, led to the trial of the modified Carnoy's solution, as suggested by Cutler and Zollinger. Since then he has cured several patients and is trying this treatment in other cases. Sufficient time has not elapsed to justify presenting the end results.

Essential Hemorrhagic Purpura—Myers points out that in essential hemorrhagic purpura the spleen is not enlarged clinically or as seen at operation or after examination by the pathologist. There may be cases in which the spleen is enlarged temporarily. The presence of thrombocytopenia, increased bleeding time, from twenty to thirty minutes or even ninety minutes or more in rare cases and a positive capillary resistance test are valuable aids in the diagnosis of essential hemorrhagic purpura. The blood coagulation is practically normal, in marked contrast with hemophilia. Acute, chronic and intermittent forms of essential hemorrhagic purpura are described. The disease should always be looked on as serious. A case that may not appear to endanger the life of the individual may terminate with tragic suddenness. The author has treated five typical cases of essential hemorrhagic purpura, all of which have been cured by splenectomy. As a temporary measure in severe bleeding from hemorrhagic purpura blood transfusion is distinctly valuable, but the good effects are likely to last only for from ten to fourteen days. Neither drugs nor thromboplastin serum are of any real value. Tying the splenic vein has been practiced by some, but, if the causative agent should prove to be a toxic substance present in the spleen, splenectomy is preferable. The usual practice is not to do a splenectomy if the red cells are below 2 million per cubic millimeter and only then after a blood transfusion.

Wire Extension in Treatment of Mandibular Fractures—To overcome the eventuality of a displaced position of the lower and upper jaws in mandibular fractures when reduction is impossible because of local edema and sepsis Brooke has applied the principles in use in the treatment of fractures of the long bones. A Kirschner's wire is passed transversely through the symphysis of the mandible and vertical weight extension is applied by means of pulleys attached to a Balkan frame. The head is held down by webbing straps to the bed. It is found that with this form of treatment the patient experiences great relief from pain and is able to open the mouth much more freely almost at once. Liquid food is given at first, followed later by soft solids. The extension is left on until the local condition in the mouth has improved to such a degree that it is possible to fit a dental splint of the usual pattern. Not only is there great relief from pain but the position of the fractured fragments is greatly improved and alignment is restored.

Diphtheroid Bacillus from Fatal Case of Meningitis—Gibson describes a fatal case of meningitis due to an organism resembling that (*Corynebacterium parvulum*) described by Schultz and his co-workers. The lesions produced appear to have resulted from invasion by a nontoxicogenic type of diphtheroid bacillus. A study has been made of its morphologic, cultural and biochemical characters and of its pathogenicity. It is highly virulent for rabbits, guinea-pigs, rats and mice and its effect is not neutralized by the antitoxins of *Corynebacterium diphtheriae* or *Corynebacterium ovis*. Efforts to demonstrate an exotoxin have failed and indirect evidence has been presented suggesting that the pathogenic effects are not due to toxic action.

Liver Changes in Exophthalmic Goiter—Cameron and Karunaratne attempt to show by grouping their thirty cases that a certain proportion of fatal exophthalmic goiter cases (about two out of three) display changes of the liver independently of passive venous congestion. They find it possible to distinguish between cases in which passive venous congestion, usually the result of cardiac failure is primarily responsible for the pathologic alterations and those in which the changes are independent of stasis. The latter however, may be complicated by venous congestion. In their thirty cases, ten showed various grades of nutmeg liver, of the remaining twenty, six presented some evidence of stasis also. Fatty change has been an almost constant finding (twenty-six cases), and they attach little significance to it. When it is associated with definite necrosis, they regard the resulting condition as evidence of a severe toxemia and in all probability the basis of the more chronic changes, which they have called atrophy and cirrhosis. They consider that the cases with chronic changes of atrophy,

fibrosis and regeneration form a group in which the frequency of occurrence and the constant pathologic picture must be related causally to the complex of exophthalmic goiter. They recognize three types of change in the liver associated with exophthalmic goiter: (1) cases with acute damage (marked fatty change and/or acute liver necrosis), (2) cases with evidence of progressive damage (various stages of cirrhosis), and (3) arrested cases (nodule formation, atrophy).

Hyaline Change in Basophil Cells of Pituitary—Crooke discusses a hyaline change in the basophil cells of the pituitary gland that does not appear to be an expression of cell degeneration in the ordinary sense but is probably an expression of altered physiologic activity. It was found in slight amount in a few basophil cells of the anterior lobe in only nine out of some 350 pituitary glands from various conditions in which the syndrome attributed to basophil adenoma was absent. Its presence in examples of the different conditions in which it was thus found was inconstant and exceptional. It was found in large amount in many basophil cells in the acini of the anterior lobe in all twelve available examples of the syndrome attributed to basophil adenoma, whether this was associated with a basophil adenoma, a neoplasm of the thymus or a neoplasm or hyperplasia of the adrenal cortex. Analysis shows that this conspicuous amount of hyaline change was the only abnormality common to all twelve examples of the syndrome, and it is concluded that it is the abnormality of fundamental significance.

Anemia in Chronic Rheumatic Diseases—Collins has observed twelve patients with chronic rheumatism and a severe or moderate anemia, who were given massive doses of iron and observed for periods up to twenty-one days, seven totally failed to respond and only two showed any marked improvement. Anemia, due to a diminished hemoglobin content of the blood with a relatively insignificant fall in the red cell count, is common among patients having chronic rheumatic conditions. The more severe degrees of anemia are seen almost entirely in cases of atrophic (rheumatoid or 'infective') arthritis. Deficient gastric secretion is not a constant factor in the production of anemia in these cases. Anemia of equal severity is encountered in cases with normal fractional test meal curves, as in cases with deficient acid secretion. There is no specific anemia accompanying the chronic rheumatic conditions. The anemia is a simple hypochromic one secondary to the disease process.

Papilledema Caused by Cervical Cord Tumor D McAlpine—p 614

Right-Sided Eventration of Diaphragm—Nicholas and Nussbrecher report a case of right-sided eventration of the diaphragm in the differential diagnosis of which paralysis of the diaphragm, eventration, hernia and absence of the right half of the diaphragm was considered. The negative history and the roentgenographic and clinical observations ruled out the first, and the roentgenogram showing an unbroken dome of the right side of the diaphragm eliminated the third and fourth possibilities. Therefore the diagnosis of right-sided eventration was the only other possibility and it was concluded that it was of congenital origin. The authors warn against indiscriminate needling of the chest in obscure cases, because there is great danger of perforating a viscus unless eventra-

tion or hernia of the diaphragm has been eliminated. The condition gives rise to hardly any symptoms, and the likelihood of serious disability in the future appears remote.

Acetylsalicylic Acid Poisoning—Dyke describes a case of poisoning by acetylsalicylic acid in which the clinical manifestations pointed to a profound disturbance of metabolism and to toxemia with a heavy incidence on the higher nervous centers. In the early stages the extreme hyperpnea was a marked feature. If the hyperpnea had been due to actual liberation of acid radicals from the ingested compound, it might have been supposed that the urine would be strongly acid, but the urinary pH was found to range from 5.8 to 6.4. Evidence of the widespread nature of the toxemia was afforded by the urine, which showed (in addition to acetone) bile salts, albumin and granular casts, which made it evident that both the liver and the kidneys were damaged severely. Albumin was present at first in large amount and on the fifth day was still present in traces, bile salts remained present in fair amount throughout the period of observation. The temperature ranged from normal to 101 F during the first four days. No physical signs indicative of inflammation that might account for the pyrexia could be found. The obvious indications for treatment were to correct the dehydration, combat the acidosis and support the liver against further damage. To this end dextrose-containing fluids were pushed in every possible way. The beneficial effect of lumbar puncture was striking, on both occasions on which it was performed it was followed by a sudden and definite improvement in the general condition. The very strong reaction with ferric chloride given on both occasions by the cerebrospinal fluid would indicate the presence in it of large amounts of the drug, and it is reasonable to suppose that benefit was due to removal from contact with the central nervous system of fluid saturated with the noxa. The beneficial effect of drainage of the cerebrospinal fluid in the present case is in conformance with general experience in barbiturate poisoning, in which also the noxa is taken up in large amount by the fluid.

- Complications of Adrenalectomies Arkannikowa—p 547
- Evolution of Sacral Methods in Operation for Rectal Cancer F Mandl—p 566

Treatment of Cystic Mastitis by Estrogenic Substance—Dahl Iversen states that the characteristic sign of cystic mastopathy is the appearance of cysts of the galactophore canals and lobules, all the new growths are irregular, and the pericanalicular and periacinous connective tissues proliferate considerably and become the site of a round cell infiltration. A number of theories have been advanced to explain these changes, among them that the primary factor is a dystrophy or senile regression of hormone secretion. The author observed the effects of ovarian hormones on the breasts of noncastrated rabbits and of infant and adult female guinea-pigs. Both estrogenic substance and lutein were used in the injections. Several results were common to the two substances. The hormones caused only a physiologic hyperplasia when administered in large quantities. The glandular system dilated uniformly and to a greater degree after the administration of lutein. The lumens were filled with a homogeneous eosinophile secretion. The epithelium kept its normal aspect and neither atrophied nor proliferated toward the lumen. Neither the pericanalicular nor the periacinous connective tissues proliferated. Dahl Iversen concludes as a result of these observations on fifty-four animals and thirty-three controls that no changes comparable to cystic mastopathy result from the administration of estrogenic substance or lutein. There is incontestable evidence, however, that estrogenic substance often has a favorable subjective as well as objective effect in human cystic mastopathy. The action on the diseased breast, therefore, seems to differ from that in the normal animal.

Sedimentation of Erythrocytes—Merkelbach points out that the question is often asked whether a micromethod gives just as reliable results as the macromethod in the determination of the sedimentation speed of the erythrocytes. The micromethod has the advantage of making a venous puncture unnecessary. The author made comparative tests with the Westergren method and the micromethod of Langer. On the basis of observations on 256 patients, the author reaches the conclusion that the micromethod of Langer cannot be the method of choice for the determination of the sedimentation speed of erythrocytes, for its results differ too greatly from those obtained with the Westergren method. The author considers a greater uniformity advisable in the determination of the sedimentation speed of erythrocytes and for this reason advises adoption of the Westergren method as the standard method.

- *Cycle of Development of Oxyuris in Intestine of Man G Penso—p 1943
- Cyst of Mesentery Case. G Muzzarelli—p 1950

Life Cycle of Oxyuris in Man—Penso calls attention to the importance of the life cycle of Oxyuris, which passes the adult and coupling phases of its life in the lumen of the intestine. The females, after coupling, perforate the intestine and pass from the lumen to the submucous membrane of the intestinal walls. There they lay eggs, the larvae of which, after development, perforate the intestinal wall and pass from the submucous membrane to the lumen of the intestine for repetition of the same cycle. The biologic cycle of Oxyuris lasts twenty days. The author proves that there is no auto-infestation by Oxyuris. The persistence of the infestation and the difficulties

of the treatment are due to the duration of the biologic cycle, on the one hand, and to the fact that anthelmintics kill the parasites in the lumen of the intestine but cannot act on those lodged in the submucous membrane of the intestine, on the other. The author believes that good results might be secured by administering anthelmintic drugs for three consecutive days, at intervals of twenty days. However, because of the possibility that different groups of Oxyuris might have their cycles between the intervals it would be preferable to find a drug, perhaps an antimonial preparation, which, given parenterally, would have a parasitic action on the parasites lodged both in the lumen of the intestine and in the intestinal walls.

- Anatomoclinical Forms of Pulmonary Syphilis in Adults D Vifoli—p 1770

New Maneuver for Abdominal Examination—Mortola describes a maneuver for abdominal examination that consists in slipping the parietal layer of the peritoneum over the visceral layer by the following technic. The patient is in the dorsal decubitus with the abdominal muscles relaxed. The physician takes between the thumbs and index fingers of both hands a large fold of the anterior abdominal wall at the lower right and left quadrants to discover any cutaneous hyperesthesia and then exercises traction on the cutaneous folds. When the parietal layer slips over the visceral layer in the pathologic zone an intense pain is produced. The positive results are of value in the diagnosis of chronic conditions of the abdomen, especially in chronic appendicitis. In these cases it coexists with a positive McBurney sign. The maneuver gives also positive results in acute appendicitis and in tuberculous peritonitis without ascites. The fact that the reaction is positive in many cases after appendectomy and becomes negative when the peritoneal inflammation subsides proves that the reaction is not appendicular but peritoneal. The intensity of the reaction is related to the peritoneal inflammatory process. In all cases in which the maneuver provoked pain in one or both sides of the abdominal surface, unilateral or bilateral lesions of the peritoneum were found at operation. The author performed the maneuver in about 130 cases, in twenty-seven of which operation was performed.

- Experiences with Physiologic Tendon Transplantation on Feet in Poliomyelitis F Mommsen—p 599

Substitutes for Blood—Konrich points out that in severe acute loss of blood the best treatment is blood transfusion. However blood transfusion involves a number of factors, such as suitable donors, tests and instruments the smooth collaboration of which may be impossible in rural regions or in certain emergencies. It would be desirable to find a suitable substitute for blood, which could be kept in readiness like other injection fluids. The author made tests on 360 rabbits, employing simple bleeding as well as the so-called washout experiment. He made comparative tests with physiologic solution of sodium chloride, a dry and a fluid preparation which, in their composition, correspond to the blood salts, and Tyrodes solution and serum. It was found that the quantity of blood the loss of which is fatal varies greatly, namely, between 1.57 and 4.63 per cent of the body weight. The isotonic solution of sodium chloride was found to be inferior to all other fluids that were tried. The solutions of the blood salts were more favorable, but even their efficacy was considerably inferior to that of serum. The efficacy of all solutions could be noticeably increased by adding to them rabbit erythrocytes removed from the serum. Death from loss of blood is not primarily due to heart failure but to failure of the respiration. The inadequate filling of the vascular system

is not the cause of death, at least not the chief cause. Death is caused not so much by a deficiency of erythrocytes as by a deficiency in serum.

Severing the Connecting Bridge of Horseshoe Kidney—Chwalla describes two cases of horseshoe kidney in which he performed dissection of the isthmus more than ten years ago. In these two cases all symptoms of the horseshoe kidney were absent ten and fourteen years after the operation. He thinks that this proves the suitability of the intervention. His two patients were women.

Histidine Therapy in Gastrointestinal Ulcer—Bauke says that, on the basis of observations in forty-six cases, he is able to corroborate the favorable results that others obtained with histidine in the treatment of gastro-intestinal ulcers. He emphasizes that the selection of the cases is highly important because histidine monohydrochloride produces the best results in new gastro-intestinal ulcers, whereas it produces as a rule only symptomatic effects in the chronic relapsing forms. The dosage must be individualized. The number of injections varies between eighteen and twenty-five. The administration of histidine in tablet form is much less effective than the parenteral administration, and the combination of oral and parenteral medication increases the action only slightly. Cure is indicated by disappearance of the subjective symptoms, of the traces of occult bleeding and of the roentgenologic signs of niche formation and by the increase in weight. The incidence of roentgenologically demonstrable cicatrization is higher after treatment with histidine monohydrochloride than after the formerly customary therapeutic methods. The average increase in weight is from 4 to 7 Kg. The gastric secretion and motility are not influenced by the histidine treatment. The author recommends the therapy for use on a larger material.

- Special Forms of Gastrogenic Anemia K. Wotzka—p. 1548
- Essential Hypochromic Anemia K. Jensen—p. 1550
- *Comparison of Thrombocyte Counts According to Fonio and Jürgens F. Gerloff—p. 1557

Intravital Examination of Bone Marrow—Henning, in collaboration with Korth, devised a new method for the withdrawal of bone marrow, a diagnostic sternal irrigation. Following anesthetization of the skin and of the periosteum, the cannula attached to a record syringe containing 0.5 cc. of the irrigation fluid, is pushed vertically into the sternum. After trying different types of trocars the authors found that a beveled hollow needle is more effective for the perforation of the bone. After the medullary cavity has been reached, irrigation is begun. The plunger of the syringe is pressed downward, which proves easy if the needle is in the correct position. As the result of the increased pressure in the medullary space, the patient feels a pain. The fluid is forced out and this is immediately followed by aspiration. A fluid having the appearance of leukemic blood appears in the syringe. The cannula is removed and the site of puncture is covered by a sterile plaster. Preparations are made as in the case of blood smears. The authors used in each case May-Grunwald, Giemsa and peroxidase stains. The advantages of this method are that the cannula is simpler because it works without a mandrin, there is no time lost in changing the mandrin and attaching the point, the hollow needle penetrates the bone readily, the readiness with which the irrigation fluid enters indicates the correct position of the instrument, the irrigation tears off a sufficient mass of cells so that the puncture fluid appears in the syringe immediately following the aspiration, and, since the irrigating fluid contains anticoagulating substances (finally a solution of sodium citrate was used), it is unnecessary to be hasty. The author emphasizes that this method is not only more simple but also more rapid than the method of Arinkin. After describing the cell morphology of the normal bone marrow, he reports the

aspects of the bone marrow in the various blood diseases. He performed approximately 200 punctures and only once failed to obtain marrow. He hopes that the intravital examination of the bone marrow will soon acquire a place beside the cytologic examination of the blood. The systematic comparison between the site of blood formation and the peripheral blood will be a great help to pathologic physiology, diagnosis, therapy and prognosis.

Thrombocyte Counts—Gerloff points out that the literature reports more than fifty different methods for the determination of the number of thrombocytes. At present the method of Fonio is most widely used. However, this method does not reveal the correct number of thrombocytes. The author's comparative tests with Fonio's method and the one described by Jürgens disclosed that the values obtained with these methods stand in a ratio of about 1:276, the method of Jürgens giving the higher numbers. He found that the lower numbers detected with the method of Fonio are due to the fact that a large percentage of thrombocytes are destroyed. He shows that the method of Jürgens is a simple and exact method in which the destructive influences are limited to a minimum.

- Significance of Determination of Rest Nitrogen for Clinic of Acute Pancreatic Disturbances F. Bernhard—p. 398

Universal Donor in Blood Transfusion—Hesse says that until recently it was generally asserted that persons in blood group O are universal donors. A number of authors even suggested that in time of war only blood of group O should be used, so as to make the determination of blood groups unnecessary. The author asserts that recently there has been an increase in the number of cases in which hemolysis followed the transfusion of blood from a universal donor into a patient with another blood group. He found forty-six cases reported in the literature, twenty of which were fatal. He emphasizes that the transfusion of large amounts of blood (more than 200 cc.) may lead to 'retrogressive' agglutination and hemolysis particularly if the titer of the donor's serum is too high compared to the erythrocytes of the recipient. Investigations were made on the titers of 104 universal donors. In more than 42 per cent the titer exceeded 1:32 with the erythrocytes of group A, and in more than 32 per cent it exceeded 1:32 with the erythrocytes of group B. The author says that such a titer already involves danger of 'retrogressive' agglutination. In fourteen cases the titer was 1:128 and in three cases 1:256. The transfusion of blood from a universal donor with a titer of 1:16 causes no symptoms. However, in cases in which the titer was high or of moderate height, signs of hemolytic shock appeared. In the case of transfusion of blood of the same group the clinical observations disclosed no deviations from the normal, whereas the transfusion of blood from a universal donor produced considerable increases in the pulse frequency (up to forty beats). This indicates that the nervous system is extremely sensitive toward discrepancies in the blood groups. The transfusion of blood from universal donors is especially dangerous if the recipient belongs to group A, for fifteen of twenty-two cases of hemolytic shock were of this group. The author reaches the conclusion that there are no universal donors in the strict sense of the term and that transfusions should be made only within the same blood group. If in case of emergency a universal donor has to be used, not more than 200 cc. should be given and even then the transfusion is permissible only if the erythrocyte count of the recipient has not gone below two million and the titer of the donor's serum with the erythrocytes of the recipient does not exceed 1:16. Of course, if it is a question of life and death and only a universal donor is available, the lesser of two evils should be chosen and transfusion tried.

Function of Greater Omentum—To obtain information about the function of the greater omentum, Ueda and Mabuchi studied the effect of its extirpation on the organism of animals.

First they made histologic studies to determine the changes in the abdominal organs following extirpation of the omentum. Quite early they found degenerative changes of different degrees in the liver, spleen, kidney, mesenteric lymph nodes and stomach. Later they observed enlargement and proliferation of the histiocytes in the liver, spleen and mesenteric lymph nodes which they consider vicarious manifestations of the reticulo-endothelial system. They describe serologic studies in which they observed that rabbits without omentum have a higher mortality following the injection of bacterial toxins than normal rabbits. Other studies were concerned with the effects of the extirpation of the greater omentum on the iron metabolism of the various organs and on the blood. The authors gained the impression that the omentum is a sort of protective apparatus against toxic substances and exerts a regulating influence on the iron metabolism. The second part of the report is concerned with experiments on the function of the greater omentum in the metabolic processes. It was observed that in rabbits the removal of the greater omentum influences the metabolism of the carbohydrates, of the protein bodies and of the fat and lipid substances. The metabolic changes that develop following removal of the spleen differ in their pathogenesis from those produced by the total extirpation of the greater omentum. The omental extirpation causes a certain fluctuation in the liver glycogen. The weight decreases gradually and usually fluctuates in proportion to the glycogen content of the liver.

Sodium Chloride Therapy in Addison's Disease S Siwe—p. 1359
Iodine Metabolism in Persons with Goiter L Scheffer and L von Megay—p. 1360

Human Milk as Hemostatic—Sole gives a summary report of the hemostatic action of human milk which he discovered in 1931. Human milk surpasses all other hemostatics in vitro as well as in the patient. However, colostrum is ineffective and the hemostatic action develops completely between the fourteenth and the thirtieth day of lactation, but after that it remains practically the same throughout the period of lactation. Only the milk of entirely healthy women (without febrile diseases) should be used. Human milk was found to accelerate the coagulability of animal bloods. The principle in human milk which effects the acceleration of the coagulation adheres to the suspended fat particles and can be separated from the milk by centrifugation. This principle is not soluble in alcohol, ether or acetone. The author describes a method for the preparation of a powder, which contains chiefly the coagulating principle and from which aqueous suspensions can be prepared. He discusses the properties, the nature and the purpose of the coagulating principle in human milk. Human milk has a hemostatic effect only when applied locally whereas enteral or parenteral (intramuscular) administration has no effect on the coagulation of the blood. The author applies the milk by means of iodoform tampons that have been saturated with it. The practical results of the local application of human milk are demonstrated on the basis of the case histories of hemophilic patients (operations and injuries). In such cases and in thrombopenic hemorrhages it produced favorable results.

New Pancreatic Substitution Preparation with Greater Lipatic Action L. Vogel and P. Lacerenz—p. 1393

Diastolic Venous Pulse Wave in Tachycardia—Misske shows that in the venous pulse curve there appears in addition to the a wave, indicative of an auricular contraction, and the v wave, as a manifestation of the filling of the right auricle during the ventricular contraction, a third elevation (d) which Wenckebach designated as the systolic-diastolic marginal wave,

or simply marginal wave, because it marks the boundary between the evacuation and the filling of the ventricle. The author explains the development of this third wave and shows that it is of especial diagnostic value. He made investigations which convinced him that the behavior of the d wave in tachycardia is determined by the beat frequency but that the changes or deviations in the d wave are not always the same in cases of equal pulse frequencies without it being possible to find a definite reason for this. Up to a pulse rate of 106 the d wave shows no great changes, for these appear only in case of higher frequencies. They can be classified into three groups. In the first group there may be considerable flattening up to complete disappearance. In the second group d is indicated only in the lower course of the systolic declivity, or it is indicated by a break-off and to a certain extent it appears as the prolongation of the systolic slope. In both groups d is immediately followed by the auricular a wave. In the third group d is prematurely interrupted by the subsequent a wave, or its peak or its ascending branch blends wavelike with the subsequent a wave. That in a case of identical pulse frequencies the deviations of the d wave may differ was observed in two cases with frequencies of 131. In one of these it was indicated as a break-off at the foot of the systolic slope, whereas in the other it appeared as a shallow wave, and in a case with a frequency of 129 it was elevated and blended with the subsequent a wave. The author describes several characteristic venous pulse curves in tachycardia. One illustration depicts the curve of the venous pulse in exophthalmic goiter. Another outlines the venous pulse in tachycardia caused by endocarditis and in which the diastolic wave was missing. A third shows blending of the diastolic wave with the subsequent presystolic wave in a case of exophthalmic goiter (caused by iodine) with a pulse frequency of 140, a prolonged transmission time (PQ 0.22 second) and a basal metabolic rate of 83.3 per cent, and a fourth shows the venous pulse curve of the same patient when the pulse frequency was 120, the PQ 0.21 second and the basal metabolic rate 50 per cent. That the deviations of the diastolic wave are caused entirely by the accelerated heart action is proved by the observation that it becomes more and more shallow with increasing cardiac frequency and is only indicated or disappears entirely in frequencies of 150 and more.

Modification of Horse Serum by Ultraviolet Irradiation—Kallós and Kállós-Deffner point out that studies by Pick and by Landsteiner disclosed that relatively slight changes in the chemical structure of antigens produce considerable changes in their biologic properties. They describe their own studies conducted to determine what effect irradiations with ultraviolet rays have on the immunobiologic properties of a protein antigen. They found that intensive ultraviolet irradiation lasting at least twenty minutes is capable of counteracting the shock producing action of horse serum, while the neutralization capacity for specific antibodies is retained.

Protective Confinement of Asocial and Antisocial Tuberculous Patients A Rössler—p. 358

Tuberculosis Contacts—On the basis of 1,000 cases that were under observation in the welfare station for tuberculous patients in Jena, Liu demonstrates 1. The importance of early examination of the persons who are in contact with a patient who has open tuberculosis. Tabular reports indicate that, if these examinations are made early, 0.72 per cent of these persons are found to have an infectious tuberculosis, whereas, if these examinations are postponed their number amounts to 19.4 per cent. 2. The importance of regular examinations. Comparative tables indicate that, in case of regular after examinations, 2 per cent contract an infectious tuberculosis and 3 per cent of these terminate fatally. However, if the examinations are not made regularly, 16 per cent are found to develop infectious tuberculosis and 9 per cent of these end in death.

*Experiences with Chemical Diagnosis of Pregnancy According to Kapeller Adler (Demonstration of Histidine in Urine) K Stern—p 2305

Diagnosis of Pregnancy by Demonstration of Histidine in Urine—Stern stresses the comparatively small number of erroneous results (5.6 per cent) in the urines of nonpregnant women, but he concedes that the test gives from 15 to 20 per cent of negative results during the early period of pregnancy. From this he concludes that the positive reactions are more convincing than the negative reactions. In the more advanced stages of pregnancy, during which, to be sure, the laboratory methods of diagnosis are much less important, the reaction has a reliability of 94 per cent. But in spite of the fact that the chemical diagnosis of pregnancy by means of the demonstration of histidinuria does not attain the same degree of correctness as the Aschheim-Zondek reaction, the author does not want to reject it. He thinks that it should be used as a preliminary test because of its simplicity, inexpensiveness and rapidity, the positive outcome in connection with the clinical test making the existence of a pregnancy highly probable, whereas the negative test could be controlled by an Aschheim-Zondek test.

Retroposition of Colon and Common Ileocolic Mesentery with Torsion Case K M Andersen—p 911

Treatment of Hematemesis and Melena with Food—Rischel says that, in 220 of Meulengracht's 256 cases of hematemesis and melena in which food was used for the treatment, the hemorrhage is ascribed to ulcerations or erosions in the intestinal tract. The mortality was about 1 per cent. Among the 206 patients in whom treatment was given up to 1935, 112 had hematemesis, ninety-four of whom had melena, and ninety-four had melena, among 192 patients, 144 were men. There were values of pathologic secretion in about 28 per cent of the cases with positive roentgenograms and in about 6 per cent of those with negative pictures. Definite roentgenologic signs of gastric or duodenal ulcer were present in about 30 per cent and doubtful signs in about 33 per cent. In a number of the remaining 37 per cent with negative roentgen results there had been constant dyspepsia of more than a year's duration directly before the hemorrhage. History of dyspeptic disorders of more than ten years standing occurred as often in the cases with negative roentgen results as in those with a positive picture, suggesting the possibility of chronic ulcer in spite of the negative results. The author says that, in addition to the more rapid restitution and blood regeneration in the patients treated according to Meulengracht than in those treated with inanition and to the reduced length of time of rest in bed, greater frequency of defecation and less tendency to constipation were noted, 175 patients were discharged without dyspepsia after an exclusive purée diet. Perforation after hemorrhage occurred in only two cases, one being a case of peptic jejunal ulcer. Blood transfusion is advised in cases of a threatening anemic condition.

*Profuse Renal Hemorrhage with Especial Regard to Cause and Treatment of Obscure Renal Hemorrhages O Mikkelsen—p 945
Umbilical Endometriosis Case E Tølbjall—p 963

Renal Hemorrhage—Mikkelsen mentions trauma, cystic kidney, floating kidney and hydronephrosis as conditions that may lead to vague renal hemorrhage and reviews the causes of profuse, continued or intermittent hematuria with or without

pain and without other symptoms, or the so called essential hematuria, classifying them on the basis of the literature as (1) histologically demonstrable changes in parenchyma, calices, papilli and pelvis, and (2) without histologic changes, disturbances of innervation or blood supply, or hemorrhagic diathesis. The largest reported number of cases of nephrectomy in obscure hematuria show nephritic changes as the cause of the bleeding. Only five cases of hypernephroma are reported. The author says that immediate nephrectomy is indicated in cases of fulminant hemorrhage if the bleeding is assuredly unilateral. In other cases the treatment is partly symptomatic, partly directed to the assumed underlying cause. Treatment is symptomatic in the rare cases of obscure bilateral hemorrhage. Expectant treatment is advised in unilateral hematuria, if the bleeding does not stop spontaneously, symptomatic treatment should be given, possibly medical treatment, as the hemorrhage often depends on focal nephritis. On recurrence, instillation of silver nitrate in the pelvis may be tried. Protein therapy is sometimes effective. The effect of roentgen treatment is doubtful. Usually only the milder hemorrhages are affected by bloodless treatment. With continued or recurring hematuria decapsulation should be considered, which is effective in most cases of nephritic hemorrhages. If hematuria recurs in spite of decapsulation, nephrectomy is indicated, provided the hemorrhage is surely unilateral.

*Retroperitoneal Hematomas C C Fleischer Hansen—p 973

*Treatment of Anuria with Intravenous Infusion of Hypertonic Sodium Sulphate Solution J E. Holst—p 989

Acute Delirium K Hermann—p 994

Retroperitoneal Hematomas—Fleischer Hansen reports a case of partially calcified perirenal hematoma in which the intumescence, originated after trauma endured for twenty five years without special symptoms. Renal function and urine were normal and the pyelogram showed slight changes. Treatment of a traumatic hematoma as such, he says, is usually not indicated, but the true hematoma without other simultaneous abdominal lesions may become so large that extraperitoneal excision is called for. Complicated organic lesions immediately after the trauma and possible infection of the hematoma somewhat later call for surgical treatment. Operation may be indicated later, often after years, because of cyst formation, pseudohydronephrosis, calcification, deficient resorption or other complications. The "spontaneous" nontraumatic hematomas are found in the kidney region even more often than the traumatic, and, while not common, are well known. In the reported case of unilateral adrenal hemorrhage the patient was admitted eight days after sudden onset of violent pain in the left renal region with subsequent daily attacks of less intense pain. Operation was contraindicated by the patient's extreme exhaustion. Necropsy revealed an intumescence the size of a man's head, consisting of coagulated blood, in which was found the normal left kidney. Remnants of the left adrenal appeared to be in the upper pole of the hematoma. Cirrhosis of the liver and arteriosclerosis of the coronary artery were found. The hematoma is thought to have originated at the time of the first grave attack. A diagnosis of perirenal hemorrhage is rarely made, the cases being generally regarded as renal tumor, perirenal abscess or ileus. Treatment should consist of lumbar incision, drainage of the hematoma and possibly nephrectomy. All graver cases have been fatal when treated conservatively. The reported mortality is about 60 per cent. Better prognosis depends on diagnosis.

Treatment of Anuria with Sodium Sulphate Solution—Holst states that, while the anuria in the two reported cases followed an attack of kidney colic and might perhaps be described as a "reflective anuria," there was considerable impairment of the kidney function with hypostenuria and, especially in the second case, renal insufficiency is believed to have existed for a longer period. Treatment with sodium sulphate resulted in rapid improvement.

SIGNIFICANCE OF PAIN AND VOMIT- ING IN CHOLELITHIASIS

ROBERT ZOLLINGER, M D
BOSTON

The susceptibility of the gallbladder and extrahepatic ducts to overdistention or inflammation from cholelithiasis makes these structures a common source of referred visceral pain. The utilization of the biliary passages in animals in the study of visceral pain has brought forth information of great value but is limited, as are all experiments involving pain in animals, because of the great barrier of speech. I have mechanically distended these passages in conscious patients at the time of operation in an effort to make observations on the important mechanism of referred visceral pain and determine whether a difference existed in the radiation and type of pain with distention of the gallbladder as compared to the common duct.

Why should patients with cholelithiasis have pain in the epigastrium, right upper quadrant or left upper quadrant, or pain referred to the back? Of the various theories proposed to explain the mechanism of referred visceral pain, two of the better known and widely accepted are those proposed by Mackenzie¹ and more recently by Morley.² A review of these theories is given in preparation for an analysis of our experimental observations to determine which theory more satisfactorily explains the mechanism of pain arising from the gallbladder or extrahepatic ducts.

According to the widely known and accepted theory of Mackenzie, pain impulses arising from the gallbladder or common duct travel to the celiac ganglion and over the right splanchnic nerves into the cord, as shown in figure 1. The Mackenzie school does not recognize true visceral pain as such but believes that these impulses set up an irritable focus in that segment of the cord into which they enter, furthermore, that the pain arises from the ordinary sensory somatic impulses entering the segment of the cord already sensitized by the sympathetic impulses. According to this theory visceral disease can express itself as pain only by secondarily involving the somatic pathways either in the dorsal root ganglion or in the spinal cord. Mackenzie believed that a viscerosensory mechanism (A-Z, fig 1) accounts for the referred pain found in the epigastrium, the right upper quadrant or the back. Likewise an overflow of afferent impulses from the organ involved

would produce muscular spasm over a visceromotor mechanism (B-Z, fig 1). The surface of the peritoneum was supposed to be insensitive, but the subperitoneal layer supplied by the cerebrospinal nerves is quite sensitive. Figure 1 shows the cerebrospinal nerves ending in the subperitoneal layer. The location of the pain according to this theory should remain stationary, regardless of the size or location of the gallbladder, since the peritoneum is not involved in the mechanism.

Figure 2 demonstrates the pathways for pain in the back in cases of cholelithiasis, according to the views of Mackenzie. It has been repeatedly proved in animals that the right splanchnic nerves carry the impulses of pain from the gallbladder and major bile ducts.³ It is anatomically known that the right splanchnic nerves usually communicate with the posterior roots of the fifth to the twelfth intercostal nerves, and that the latter supply the segments of the skin in which the painful areas in gallbladder disease are commonly referred. Pain in the back is usually located in the interscapular or infrascapular region on the right side. A careful analysis will often show a similar location of pain when the patient complains of pain in the shoulder. Relatively few have discomfort in the third or fourth cervical segment, as noted following the stimulation of the phrenic nerve.

The theory of Morley is explained in figure 3. He agrees with Ryle,⁴ Hurst⁵ and others that a true visceral pain does exist and that it is usually the result of abnormal tension on the sympathetic afferent nerve endings in the muscular walls of the hollow viscera. Morley believes that visceral pain is in no sense referred to superficial structures of the abdominal wall and is a deep-seated central pain, not accurately localized. The early epigastric symptoms of appendicitis are an example of such a pain. Likewise, vaguely localized epigastric distress might be expected as an early symptom of distention of any part of the digestive tube supplied by the celiac ganglion, including the gallbladder. The pain of large bowel distention and the like is similarly referred to a lower level because of the sympathetic nerve supply. Impulses traveling over the splanchnic nerve (Z) enter the cord and are recognized by the higher centers as pain, but they do not enter into the mechanism of referred pain to the back or right upper quadrant.

Morley believes that (1) referred pain does not occur unless the cerebrospinal nerves are stimulated, (2) the peritoneum supplied by the cerebrospinal nerves is highly sensitive, and (3) the cerebrospinal nerves extend to the peritoneum (fig 3) instead of to the sub-

peritoneal layer as shown in figure 1 Capps⁷ found that the pain elicited by stimulation of the parietal peritoneum is localized with considerable accuracy by the patient, the error being less than 1 inch (2.5 cm). The pain of cholelithiasis in the right upper quadrant would indicate that the underlying peritoneum has been stimulated according to the theory of Morley. He has empha-

Fig. 1—Explanation of the theory of Mackenzie. The gallbladder is not in contact with the parietal peritoneum. The cerebrospinal nerves end in the subperitoneal tissue. A Z, viscerosensory reflex; B Z, visceromotor reflex; P C B, posterior cutaneous branch; L C B, lateral cutaneous branch; A C B, anterior cutaneous branch.

sized the change in position of the pain and tenderness as an acute gallbladder descends with an increase in size. He proposes a peritoneocutaneous radiation (A, fig. 3) all within the cerebrospinal nerves to explain referred pain, likewise, a peritoneomuscular reflex (B, fig. 3) to explain muscle spasm and rigidity. Ryle⁸ has emphasized that referred pain does not often occur from distention alone but is usually accompanied by inflammation. In practically every case of cholelithiasis there is an accompanying chronic cholecystitis which would be an adequate stimulus for the pain or tenderness in the right upper quadrant.

The explanation of Morley for the pain in the back in cases of cholelithiasis is shown in figure 4. The dotted lines represent sensory innervation by the sympathetic nerves to the visceral peritoneum. The heavy lines represent the surfaces of the peritoneum, which he believes are supplied by the cerebrospinal nerves. These sensitive nerves extend a short distance up the mesenteries and into the gastrohepatic ligament about the major bile ducts. He believes from his observations on the production of pain in patients under local anesthesia that the cerebrospinal nerves extend a greater distance into the mesenteries than was previously maintained. The inflammation about the extrahepatic ducts themselves stimulates the somatic nerves in the gastrohepatic ligament and so gives rise to localized pain in the back,

just as in the right upper quadrant. He calls attention to the frequent observation that during an operation for gallstones, following a recent attack of gallstone colic, evidence of inflammatory congestion and edema is usually found involving the gallbladder wall and adjacent bile ducts. The exact anatomic relation of the cerebrospinal nerves to the gastrohepatic ligament is not known. However, since the sensory supply of the margins of the diaphragm, both the pleural and peritoneal surfaces, arises from the lower six intercostal nerves, it is reasonable to assume that branches may extend into the adjacent tissues. In the great majority of cases the pain in the back is referred to the region supplied by one or more of the lower six thoracic nerves.

The anatomic arrangement and accessibility of the gallbladder and common duct permit the easy utilization of these structures in animals for the study of the mechanism of referred visceral pain. Schrager and Ivy⁹ have reported observations on the mechanical distention of the gallbladder or biliary passages in dogs. Their studies were undertaken primarily to give experimental evidence to the clinical observations that patients with gallstone colic have an associated inspiratory distress. They found that distention of the gallbladder caused distress, inhibition of respiration, and salivation denoting nausea in approximately 40 per cent of the dogs. Vomiting occurred only once, and then when food was in the stomach. Distention of the biliary duct caused more striking symptoms than distention of the gallbladder. Salivation or nausea always, and vomiting frequently, occurred if the pressure was above 100 mm. of mercury.

Ogilvie¹⁰ in England distended the gallbladder in a series of patients following cholecystostomy. Of course, in these patients the gallbladder was attached to the anterior wall. He found that nausea was present in four of the six cases, but no vomiting. The patients all complained of a distress resembling indigestion. The pain was roughly localized to the region of the gallbladder in four cases, to the xiphoid process in one and to the left hypochondrium in another. He concluded that accurate localization of the pain in gallbladder disease was an indication of involvement of the parietal peritoneum by an infectious process, and in the absence of infection the pain due to obstruction of the cystic duct may be vaguely localized to the upper part of the abdomen.

Fig. 2—Pathways for pain in the back according to theory of Mackenzie.

Our experimental observations corroborate his results.¹¹ We have made observations on nine women,

operated on for gallbladder disease. The complaints varied from chronic indigestion to typical as well as bizarre radiation of the pain. Chronic cholecystitis and cholelithiasis were found in every case at operation.

In seven patients the gallbladder was exposed and the stones were removed after a short gas-oxygen anesthesia. A sterile rubber balloon, carried on a sterile

cult 6 Distention of the gallbladder, producing contact with the parietal peritoneum, gave localized pain. This was markedly relieved by infiltration of the overlying abdominal wall with procaine hydrochloride. 7 Two patients did not complain of discomfort regardless of the amount of distention of the gallbladder. Our observations further indicated that 1 Mechanical distention of the common duct produced severe epigastric distress. The pain was more severe than that in distention of the gallbladder in the same patient. 2 Dis-

Fig 3—The theory of Morley. The gallbladder is in contact with the parietal peritoneum. The cerebrospinal nerves end in the peritoneal layer. A peritoneocutaneous radiation. hollow metal tube, was inserted into the gallbladder (fig 5). The tube was connected to a glass jar through which the balloon could be inflated and the amount of pressure recorded. The fundus of the gallbladder was then sealed around the rod by several silk sutures and replaced in the abdomen away from the abdominal wall. The edges of the wound were held in approximation and all gauze and retractors removed from its margins to avoid additional painful stimuli. Distention was carried out after the patient had recovered sufficiently from the short anesthesia to answer questions intelligently. In two patients the observations were made following exposure of the gallbladder under local infiltration anesthesia of the right upper quadrant. The common duct was distended in three of the nine patients by the same method and the resultant signs and symptoms were similarly recorded. The pressure applied varied between 50 mm and 150 mm of mercury.

Our observations indicated that 1 Mechanical distention of the gallbladder usually gave rise to deep epigastric discomfort, more severe but similar to the attacks of indigestion in gallbladder disease (fig 6). 2 The discomfort was not referred to the gallbladder region. 3 Distention of the gallbladder did not cause vomiting. 4 It was found impossible to reproduce the usual referred pain in the back, the infrascapular region or the right upper quadrant. 5 Objectively and subjectively the patients had respiratory difficulty when the gallbladder was distended, especially inspiratory diffi-

TABLE 1—Observations in Nine Women Who Came to Operation

| 4 | Inspiratory distress |

ty of the common duct produced vomiting in two of the three cases. 3 There was no evidence of referred pain to the right upper quadrant or to the back. 4 Inspiratory distress was present.

I have attempted to explain our observations according to the commonly accepted theories of referred visceral pain previously reviewed. Contrary to the Mackenzie theory, I believe that a true visceral pain exists. This was represented in our experiments by the consistent finding of epigastric discomfort similar to the attacks of indigestion noted by the patients previous to operation. Two of our patients had a tendency to refer their epigastric discomfort to the left upper quadrant, as they did previous to operation. Sheldon¹² has recently reported observations on a patient who complained of precordial pain. He¹³ stated that the pain was usually in the epigastrium and only several times was it referred to the precordium. The pain was never referred to the back. The pain in the left upper quadrant may represent atypical localization of the vaguely localized visceral epigastric pain. The mechanism was intact for the reproduction of referred pain in either

Fig 4—Possible pathways for pain in the back according to theory of Morley. Solid lines represent innervation by cerebrospinal nerves. The visceral peritoneum supplied by sympathetic innervation is represented by dotted lines.

13 Sheldon L. B. Personal communication to the author.

the right upper quadrant or the back, according to the theory of Mackenzie. Although the mechanical distention was an adequate stimulus for visceral pain to reach the cord by the usual route, referred pain did not result despite the fact that the majority of these patients previous to operation had pain in the back or right upper quadrant. According to the theory of Mackenzie, a previous irritable focus must have existed in the cord in several of these patients with referred pain up to the time of operation, and it is reasonable to assume that the mechanism should have been repeated following distention of these organs.

The relief obtained by infiltration of the overlying skin with procaine hydrochloride might be interpreted to favor the theory of Mackenzie. Some infer that by this method afferent somatic impulses failed to reach the irritable focus of the cord, and referred pain was

Fig 5—Apparatus used in the experimental studies

not recognized. Weiss and Davis¹⁴ believe that, since pain referred from intra-abdominal disease is obliterated or relieved by infiltration of the skin over the painful point, some weight is given to the Mackenzie theory. However, Morley believes that it is just as much in favor of his peritoneocutaneous radiation, since pain in the shoulder tip referred over the phrenic nerve can likewise be alleviated by anesthetizing the painful area. The latter pain rises from stimulation of the dome of the diaphragm, travels over the phrenic nerve and is referred usually to the fourth cervical segment, all within the somatic cerebrospinal nerves.

Since referred pain could not be reproduced by mechanical distention either in our cases or in those of Oglvie, weight is given to the argument that referred pain and tenderness are more likely to result from inflammatory lesions. The common association of cholecystitis with cholelithiasis would adequately account for the frequency of referred pain in this dis-

ease. The pain in the right upper quadrant is usually localized over the region of the gallbladder, and it is suggested that the peritoneum may enter into the mechanism of this pain. The peritoneocutaneous radiation of Morley could be used to explain this mechanism (fig 3). Since Sheehan has offered anatomic evidence in favor of afferent somatic nerves branching in the gastrohepatic ligament, I believe that these branches may come from any of the lower six thoracic nerves that supply the adjacent peritoneal margins of the diaphragm. In other words, the pain in the back in gall bladder disease is the result of direct inflammation of the cerebrospinal nerves over a mechanism similar to that in which pain is localized over the right upper quadrant.

The pathway explaining inspiratory distress is not entirely clear. It has been proved by Ivy³ that, in dogs, distention of the gallbladder or common duct produced fixation of the diaphragm. This was partially relieved by section of the right splanchnic nerve and partially relieved by section of the vagus nerve. Section of the vagus seemed to be more efficacious than section of the splanchnic, and it was necessary to cut both nerves to abolish this reflex entirely. The fixation of the diaphragm may be of cortical origin as a protective mechanism against pain.

Two of the patients had no discomfort regardless of the amount of distention of the gallbladder. Ivy recorded a similar observation in some of his experiments on dogs. The experimental observations agree with the clinical that the gallbladder in some patients can be markedly distended with stones without symptoms or with only slight discomfort. It has been shown that gallstones are discovered in about 10 per cent of the women operated on for other conditions who have never had symptoms suggestive of cholelithiasis.¹⁵

The absence of vomiting following distention of the gallbladder and the presence of this symptom when the common duct was distended is in accord with the observation on animals. Previous experimental work has shown that afferent emetic impulses from the peritoneal cavity travel with equal facility through the vagal and the sympathetic trunks.¹⁶ Perhaps, as Ivy suggests, a difference of threshold exists between the gallbladder and the biliary passages, the nerves of the gallbladder being more difficult to excite.

CLINICAL STUDY

An effort has been made during the past two years to test the clinical significance of our experimental observations. Patients were specifically questioned in regard to vomiting, shortness of breath, and the location and radiation of their initial pain. The 153 surgical cases of cholelithiasis in the Peter Bent Brigham Hospital during this period were divided into five separate groups, according to the probable location of the offending stones (table 2).

The first group consisted of forty-three cases of chronic cholecystitis and cholelithiasis with a negative history for jaundice. A second group included twenty-two cases of chronic cholecystitis and cholelithiasis with history of jaundice in which either the common duct was not explored or no common duct stone was found at exploration. However, the history of jaundice implied that the common duct had at some time been

all but the first group, therefore, there was evidence of past or present obstruction of the cystic or common duct.

A comparison was made of the incidence of vomiting, jaundice, colic, inspiratory distress and the location and radiation of the initial pain and like conditions in the various groups.

The presence of vomiting when the common duct was distended suggested that this symptom might be of value in making a diagnosis of a calculus located outside the gallbladder, especially in the common duct. Involuntary vomiting, and not induced vomiting, was included if it occurred at any time in the present or past illness. Table 2 demonstrates the high incidence of vomiting in those cases in which a stone was lodged or passed through the cystic or common duct. Vomiting occurred in only 44 per cent of the forty-three patients with chronic cholecystitis who gave no history of jaundice and in whom the stone was not found in the ampulla or the cystic or common duct. Obviously it could not be determined in what number of cases a stone might have been lodged in the cystic duct accounting for the history of vomiting. This finding agrees with the views of those who believe that patients with cholelithiasis may have nausea and induced vomiting, but involuntary vomiting indicates that a stone is located outside the gallbladder in the bile ducts. A higher incidence of involuntary vomiting was found in the cases of chronic cholecystitis in which there was a history of jaundice. Apparently in many of these cases a common duct stone had been passed or may have been overlooked at the time of operation. Vomiting occurred in 73.3 per cent of the cases of acute cholecystitis. In a large number of these cases a stone was found impacted in the ampulla of the gallbladder or in the cystic duct, which would account easily for this symptom, as shown in the next group. Involuntary vomiting occurred in 87 per cent of the cases in which a stone was found impacted in the ampulla of the gallbladder or in the cystic duct at the time of operation. The highest incidence, 91 per cent, was found in the cases of common duct stone. Our experimental observations which showed that vomiting followed distention of the

common duct, seems to coincide rather closely with the clinical observations that distention of the bile ducts, by a calculus, produced a high incidence of involuntary vomiting as compared to calculi in the gallbladder. The clinical analysis of patients with cholelithiasis has been convincing enough to make us suspicious of a calculus in the cystic or common duct in cases in which there is pronounced involuntary vomiting. Furthermore, we believe that, when vomiting has been a prominent symptom, exploration of the common duct might be considered regardless of the history of jaundice or size of the common duct, unless at operation a calculus was found impacted in the ampulla or cystic duct.

It has been taught generally that a diagnosis of common duct stone is made when biliary colic is accompanied by the classic triad jaundice, chills and fever. We found that jaundice had occurred at some time in 44.4 per cent of 153 cases. The first group of chronic cholecystitis was selected with a negative history for jaundice and the second for a positive history for jaundice. It occurred in 20 per cent of cases of acute cholecystitis and in 30.4 per cent of the group in which a stone was found impacted in the ampulla or cystic duct. The highest incidence of jaundice, 88.5 per cent, occurred in those cases in which a common duct stone was found at operation. It has been previously emphasized by Clute¹⁷ that jaundice was absent in 39 per cent of his cases of common duct stone. However, in a much larger series of cases reviewed in our hospital we found the incidence of jaundice to remain in the neighborhood of 90 per cent.

Attacks of biliary colic were recorded in a high percentage of all our cases. Perhaps a few of the patients did not actually have a typical colicky type of pain. It is significant to note that not all the patients with common duct stones gave a history of colic. Macdonald¹⁸ has recently emphasized the low incidence of colic in cases of common duct stone. He quotes Wilkie of Edinburgh as believing that patients have colic only when a calculus passes the muscular cystic duct, but no

pain in the common duct, owing to the fact that there is insufficient muscular development in the wall of the common duct to produce contraction. We believe that patients with common duct stone generally do have colicky pain, and it might be explained by overdistention of this fibro-elastic tube.

There was a low incidence of chills and fever associated with cases of chronic cholecystitis, despite the fact that a moderate number gave a past history of jaundice. Chills were present in 16.6 per cent of the cases of acute cholecystitis and 31.4 per cent of the cases of proved common duct stone. Although chills

have been associated in the classic triad indicating common duct stone, it was found in less than one third of the cases

Respiratory embarrassment may accompany any type of colicky pain, but I am convinced of its importance in the diagnosis of biliary colic. Schragar and Ivy⁹ and Crile¹⁰ have emphasized the clinical value of this symptom in the differential diagnosis of diseases of the gallbladder and biliary ducts from other disorders of the upper portion of the abdomen. That this symptom has not been looked for is evidenced by the fact that it was not mentioned in a review of 300 cases of cholelithiasis at the onset of this study. Respiratory distress was mentioned in about one fourth of our recent cases.

Pain occurred as the initial complaint in the right upper quadrant in about two thirds of all the cases. The high incidence of epigastric discomfort occurred in the acute cases and the cases of common duct stone. I believe that epigastric distress as the initial symptom indicates dilatation of the ducts, and these percentages tend to confirm that belief. It is interesting to note that the incidence of pain in the back, or referred to the back, is practically the same as that occurring in the right upper quadrant. This might be interpreted to mean that patients having sufficient inflammation of the gallbladder to stimulate the parietal peritoneum anteri-

- 8 Contracted thickened gallbladder
- 9 Dilated cystic duct
- 10 Thickening of head of pancreas
- 11 Many small stones in gallbladder and cystic duct

orly would also have an inflammatory process extending down the cystic duct to the common duct. The somatic nerve supplying the gastrohepatic ligament about the common duct would then refer the pain to the back according to the theory of Morley. The pain was present, or radiated to the left upper quadrant, in 16.2 per cent of the first group of patients who had not been jaundiced, and in a few of the others. The experimental and clinical manifestations of pain of the left upper quadrant were interpreted as an atypical localization of true visceral pain.

Table 3 is a compound of a study of 300 cases of cholelithiasis that were studied at the beginning of our experimental observations. They are included here to support the smaller series reported, covering the past two years. Involuntary vomiting occurred in some 29 per cent of the chronic cases of cholecystitis and jumped rapidly to 85 per cent in the 100 acute cases and to 89 per cent in cases of common duct stone. The incidence of jaundice was similar to the smaller group reported. Colic occurred in an increasing proportion in the acute group and common duct stone group. This incidence of colic is probably more reliable than the higher incidence reported in the past two years. Chills and fever were present in only 15 per cent, as compared to 31 per cent of our recent cases.

The clinical analysis appeared convincing enough to make us suspicious of a calculus in the cystic or common duct in cases in which there was pronounced involuntary vomiting. I believe that this symptom should

be added to the list of commonly accepted indications for drainage of the common duct, as shown in table 4. The first five indications would be obtained from the history, including the history or presence of jaundice, symptoms of cholangitis associated with cholelithiasis, recurrent symptoms after previous surgery on the biliary tract, frequent attacks of gallstone colic, and pronounced involuntary vomiting.

At operation the common duct should be explored if there is a suspicion of a stone by palpation, dilatation or thickening of the common duct, contracted, thickened or nonfunctioning gallbladder, dilated cystic duct that would permit stones to pass into the common duct, thickening of the head of the pancreas suggesting a chronic pancreatitis, perhaps the result of a calculus in the common duct, or many small stones in the gallbladder and cystic duct, which might easily pass into the common duct.

I believe that, by keeping in mind the various indications more common ducts have been explored and that this has been partially responsible for the finding of a high incidence of common duct stones. The common duct was explored in fifty-nine cases, or 38.3 per cent of the 153 cases. The common duct was usually opened after the method of Cheever.²⁰ A common duct stone was found in 59.3 per cent of the ducts explored or in 22.8 per cent of the 153 patients operated on during 1933 and 1934. According to the autopsy statistics compiled by Crump,²¹ a stone is located outside the gallbladder in more than 20 per cent of cases of cholelithiasis. The finding of a similar number of common duct stones at operation should improve the general end result following operations for cholelithiasis.

CONCLUSION

I believe that our experimental observations indicate that a true visceral pain exists.

Our inability to reproduce referred pain to the back adds weight to the argument that referred visceral pain is usually the result of inflammation, probably over a peritoneocutaneous radiation instead of a viscerocutaneous reflex.

Experimentally and clinically, inspiratory distress commonly accompanies distention of the gallbladder or extrahepatic ducts.

The experimental finding of vomiting following distention of the common duct, but not the gallbladder, has been confirmed by a clinical analysis. Furthermore, I believe that involuntary vomiting should be added to the list of commonly accepted indications for exploration of the common duct.

A common duct stone was found in 22.8 per cent of the patients operated on for cholelithiasis in the Peter Bent Brigham Hospital during the years 1933 and 1934.

Irritability and Lack of Stamina—Hess repeatedly pointed out the frequency among children of cases in which no specific symptom of scurvy can be seen but in which irritability, lack of stamina, and retardation of growth can be cured by the simple addition of more antiscorbutic food to the dietary. The interpretation of such a case is that the previous food, while furnishing enough vitamin C to prevent scurvy, had not been rich enough in this vitamin for the best interests of normal nutrition—Sherman, H. Gallstones are supposed to have been removed from the gallbladder of a living patient by Fabricius¹ in 1618, but Petit,² who published his discussions on biliary obstruction and its surgical treatment a century later, is often considered to be the founder of surgery of the gallbladder. Great improvements were made in the technic by Bobbs,³ who sponsored cholecystotomy and also by Langenbuch,⁴ who in 1882 performed the first cholecystectomy on a human being. However little mention was made of the hemorrhagic tendency of jaundiced patients until Smith⁵ called attention to it in 1891. Since that time an enormous amount of information has accumulated and as a result present methods of treatment have a more rational basis. Nevertheless the problems associated with jaundice have not all been settled, as is shown by the numerous theories concerning the factors involved.

The early investigators believed that the excess of bile pigment circulating in the blood stream was responsible for the hemorrhagic tendency. Morawitz and Bierich⁶ observed that when one part of oxbile was added to from ten to fifteen parts of dog's blood in vitro the mixture composed of bile and blood was incapable of coagulation. Since a 10 per cent concentration of bile never occurs in jaundiced patients and since anticoagulant effects were not obtained with lower concentrations, this observation could not be of clinical importance. King and Stewart⁷ then offered a different explanation, they suggested that the calcium combined with the bile pigment and rendered it less toxic. Later, King, Bigelow and Pearce⁸ concluded that, when the calcium and bile pigment combined, less calcium was available and that this caused interference with the mechanism for coagulation.

Other investigators were equally certain that the bile acids played the most important part in the process because of their ability to inhibit the coagulability of the blood in vitro. Morawitz and Bierich⁶ felt that there was not a sufficient concentration of bile acids in the blood of patients to inhibit clotting. Hoppe⁹ used 30 liters of urine of jaundiced patients before obtaining a positive test for bile acids, but later experiments

have not substantiated his results. Malkoff¹⁰ demonstrated both clinically and experimentally that early in the course of the disease bile acids are present in the urine of patients who have obstructive jaundice but that they tend to decrease in concentration if the jaundice persists. Foster, Hooper and Whipple¹¹ and Wangenstein¹² made similar observations. Wangenstein¹² also reported that not only did excretion of the bile acids diminish but the synthesis of bile salts was interfered with. The recent work of Brakefield and Schmidt¹³ and of Snell, Greene and Rowntree¹⁴ agreed with these results. Therefore it appears safe to assume that neither the bile pigments nor the bile acids per se are responsible for the bleeding of patients who have obstructive jaundice.

Wright¹⁵ was probably the first to suggest the use of calcium in cases of hemophilia and internal bleeding, and Mayo Robson¹⁶ the first to propose its use to stop the bleeding in cases of obstructive jaundice. Boggs¹⁷ found a decrease in the coagulation time after the administration of calcium to rabbits both orally and intravenously. Rey¹⁸ observed a similar phenomenon in dogs. Lee and Vincent¹⁹ found that the addition of calcium chloride to the blood of jaundiced patients in vitro shortened the coagulation time. According to Schmerz and Wischo,²⁰ the intravenous injection of calcium lactate into normal persons shortened the coagulation time. Walters²¹ has emphasized the use of calcium chloride as a preventive of hemorrhage in cases of obstructive jaundice. Kirk and King²² and Emerson²³ reported a moderate reduction in the total calcium content of the serum in cases of jaundice but found a greater reduction in the ultrafiltrable or diffusible fraction. Buchbinder and Kern²⁴ noted a reduction in the calcium content of the serum in three cases of jaundice. Favorable results were obtained with parathyroid extract by Cantarow, Dodek and Gordon²⁵ in the treatment of jaundiced patients who showed a tendency to bleed. In the opinion of these investigators

the hormone acted as a mobilizer of calcium, which in turn increased the coagulability of the blood and was instrumental in diminishing the permeability of the capillary walls. King, Bigelow and Pearce⁸ found changes of osteoporosis in the bones of patients who had obstructive jaundice. However, Halverson, Mohler and Bergeim²⁰ expressed the belief that reduction of the serum calcium content in jaundiced patients is more apparent than real. In addition, Hammarsten²⁷ showed that the interaction of thrombin and fibrinogen to form fibrin does not require the presence of calcium. Vines²⁸ and Stuber and Focke²⁹ had similar experiences. Snell, Greene and Rowntree³⁰ found no change in the serum calcium content either in cases of experimental obstructive or in other forms of jaundice. Later, Snell and Greene³¹ concluded that there was no correlation between either the total or the diffusible content of calcium of the serum on the one hand and, on the other, either the serum bilirubin or the delay in the coagulation time of the blood in the presence of jaundice. From this discussion it appears that there may be some disturbance of the blood calcium in cases of obstructive jaundice but that its relationship to hemorrhage is rather indirect and at present unknown.

Fonio³² has administered an extract containing lipoids and blood platelets, which has yielded results in the treatment of jaundiced patients who were bleeding. However, except rarely there is no evidence of a quantitative deficiency of blood platelets either in obstructive jaundice or in hepatic necrosis associated with severe hemorrhagic tendencies. On the other hand, it is possible that there is a qualitative alteration.

Irradiation of the spleen appeared to lower the clotting time of normal blood and led Stephan³³ to employ that plan to stop bleeding. Tichy³⁴ suggested irradiating the liver. Foster and Whipple³⁵ expressed the belief that the value of this treatment is attributable to an increase in the blood fibrin content.

Many experiments and clinical observations have demonstrated that the liver has an important function to perform in association with coagulation of the blood. Bohr³⁶ ligated the celiac and mesenteric arteries and observed that specimens of blood taken four hours later would not clot for two hours. Doyon,³⁷ Doyon, Morel and Billet³⁸ and Doyon, Morel and Kareff³⁹ had simi-

lar experiences after injecting atropine into the mesenteric vein of the dog and after administration of overdoses of chloroform. Kerr, Hurwitz and Whipple⁴⁰ produced necrosis of the liver in dogs by the subcutaneous injection of phosphorus and found that the blood of the animals would not clot. Doyon and Kareff⁴¹ also excised the livers from dogs and observed that the blood failed to clot. Thus it would seem that there might be something present in the liver which is essential for the clotting of blood.

The bleeding which occurs in cases of jaundice may be attributable to a lack of fibrinogen, as has been suggested. Foster and Whipple³⁵ stated that the liver is the main potential source of fibrinogen in the body. They showed that although the clotting time does not vary profoundly with a change in the blood fibrinogen content, low values for fibrinogen may be responsible for the clots being too weak to act efficiently. Colbeck⁴² also found low values for fibrinogen in some cases of obstructive jaundice, and expressed the belief that in these instances the liver was incapable of responding in a normal manner to a demand for a raised blood fibrinogen content. On the other hand, Williamson, Heck and Mann⁴³ stated that the liver is not necessary for the regeneration of fibrinogen. Linton⁴⁴ observed that in cases of obstructive jaundice there was no deficiency of blood fibrin. In contradistinction to this, Moss⁴⁵ and Snell⁴⁶ found that there is really an increase in the amount of fibrinogen relative to the extent of the change in the liver, and they concluded that the hemorrhagic tendency of jaundiced patients is not associated with a deficiency of fibrinogen in the plasma.

Some investigators have expressed the belief that the damaged liver of a jaundiced patient produces an excess of an anticoagulant substance that prevents the blood from clotting. Howell⁴⁷ expressed the opinion that such a material is responsible for the fluidity of the blood and that an excess may be the cause of hemorrhage in cases of hemophilia and jaundice. Doyon and his co-workers⁴⁸ injected atropine, oxbile and bile acids into the mesenteric veins and common bile ducts of animals and produced incoagulability of the blood, but they failed to obtain the same result after systemic injection. Their experiments seemed to substantiate the theory that the damaged liver produces an anticoagulant substance. Boggs⁴⁹ also observed that injection of thymus and liver extract from dogs often results in incoagulability of the blood. In addition, Denny and Minot⁴⁰ noted that stasis of the blood in the liver

caused an increase in the antithrombin content of the blood. However present methods of estimating the concentration of heparin-like substances in the blood are subject to so many errors that the results are not reliable.

According to Carr and Foote¹ the bleeding of jaundiced patients is attributable to seepage through an inefficient clot, although the blood clots as rapidly as normally. They expressed the belief that the clot which is formed is influenced by the collection of intermediate products of protein metabolism, such as cysteine and related forms of mercaptan, so as to produce a non-retractile friable jelly instead of a strong occluding mesh. They employed brombenzene experimentally in the treatment of the bleeding associated with jaundice and had good results. However, the clinical application of this work has yet to be proved.

The fact that hemorrhage with jaundice still occurs, although present methods of treatment have reduced its incidence, shows that further search must be made before it will be possible to eradicate this serious complication completely. The recent work of Snell and Adams⁵⁰ has directed attention to several new factors and it is on these phases of the problem that the present paper is based.

THE CLINICAL OCCURRENCE OF THE TENDENCY TO HEMORRHAGE

There is no close relationship between the tendency to bleed and the duration of obstructive jaundice, but in a general way the hemorrhagic tendency is enhanced as the period of obstruction is prolonged. When the obstruction is caused by a malignant process, the liability to hemorrhage is also magnified because of the more extensive hepatic damage that occurs under these conditions. Likewise, the depth of the bilirubinemia does not seem to be an invariable controlling factor in the bleeding, but certainly more severe bleeding is seen in deeply jaundiced patients. Long continued intermittent obstruction also appears to produce a hemorrhagic tendency that is almost certainly the result of progressively increasing damage to the liver. It should also be mentioned that bleeding attributable to hepatic disease has been known to take place in the absence of clinical jaundice. Linton⁵¹ reported observing a hemorrhagic tendency in patients with biliary fistula who did not have jaundice. Judd⁵² also encountered this situation several times. In addition Walters⁵³ noticed similar phenomena in a case of carcinoma of the liver. However, the tendency to bleed is associated more frequently with severe damage to the parenchyma of the liver, such as is present with acute yellow atrophy or the degenerative changes which occur secondary to biliary obstruction, than with any other type of lesion. These observations suggest that the degree of injury to the hepatic parenchyma may be the most important factor in the production of hemorrhage in cases of hepatic disease. Further credence is also given to such an opinion, for there appears to be no tendency to bleed in cases of hemolytic jaundice, and according to Wangersteen⁵² the incidence of spontaneous hemorrhage in cases of catarrhal jaundice is exceedingly low. In both of these conditions the amount of hepatic injury is comparatively slight.

Almost every one is familiar with the beneficial effects of the transfusion of blood, which are reflected in the decrease in the coagulation time of the blood and in the general improvement of the jaundiced patient. However, the reason for these changes has always been obscure. The method of transfusion employed most frequently at present involves the use of sodium citrate as an anticoagulant. Because sodium citrate in itself has been shown to lower the coagulation time, it might be argued that the improvement that follows the administration of citrated blood is attributable to the sodium citrate. However, this cannot possibly be true, for numerous investigators have found that equally good, or even better, results can be obtained by utilizing whole blood. For several months we adhered to the plan of using whole blood in transfusions in order to obtain comparative data on a large series of jaundiced patients. For a while we thought that there was less tendency to bleed than there had been when we used citrated blood, but further experience seemed to indicate that the transfusion of citrated blood is of as much value as is the transfusion of whole blood. The best method of preventing hemorrhage is to give one or more transfusions of blood before operation, in some cases the transfusion of blood should be carried out both before and after surgical correction of the condition.

It should be mentioned at this point that hepatic insufficiency and renal insufficiency are two other surgical complications that must be kept in mind when jaundiced patients are being treated. Since an injured liver can utilize carbohydrates more readily than it can utilize any other nutrient substance, large quantities of a 10 per cent solution of dextrose should be given intravenously both preoperatively and postoperatively. This measure should be further supplemented by a high carbohydrate diet. The increased intake of fluid, just described, serves a double purpose in the presence of jaundice for it may also improve elimination through the damaged kidney. Some, if not all, of these therapeutic measures should be continued throughout convalescence. Under such a plan of treatment the mortality was only 4.3 per cent following operations performed on jaundiced patients at the clinic in the past year.

The risk of operations on the biliary tract is materially increased if the procedure is undertaken after the development of an obstruction of the biliary tract and of an associated infection in the liver and pancreas. The patients operated on in 1934 illustrate this point very well. In 617 consecutive cases, cholecystectomy or cholecystostomy was performed for acute or chronic disease confined to the gallbladder with the extremely low mortality of 0.97 per cent. This figure may be contrasted with the mortality of 2.65 per cent for 867 consecutive cases in which complicating factors necessitated operating on the common or hepatic ducts. One hundred and seventeen patients in the latter group were jaundiced at the time operation was undertaken.

The operative risk in cases of jaundice deserves further elaboration. In all, 207 jaundiced patients were operated on at the clinic in 1934, with a mortality of 4.3 per cent. Failure to recover was attributable for the most part to hepatic insufficiency or hemorrhage. The variety of measures advocated for the control of the hemorrhagic tendency in the jaundiced patient is in itself evidence of the lack of specificity of any of these measures. Relief from the underlying condition is the first consideration. When possible, operative

measures to relieve biliary obstruction should be instituted as promptly as possible after preoperative preparation. Often cycles of bleeding can be observed, especially if a determination of the coagulation time is made daily or on alternate days. It is well to take advantage of this natural variation in choosing the time for a necessary surgical procedure.

Each of the patients in this series who died had a rather marked degree of jaundice and the serum bilirubin value was more than 5 mg per hundred cubic centimeters. In two cases the concentration of serum bilirubin was more than 10 mg per hundred cubic centimeters and in three it was more than 20 mg. There is no known method by which it is possible to determine conclusively whether the liver will resume its excretory function if biliary obstruction is relieved surgically. Consequently, the surgeon is often misled in regard to the risk involved when operative measures are undertaken. In our experience the level for serum bilirubin gives the most information concerning the degree of parenchymal injury. Although patients who have moderate icterus cannot be insured against hepatic insufficiency, and some of those who have marked bilirubinemia may have a comparatively smooth convalescence, in general the higher the value for serum bilirubin the greater the likelihood that serious hepatic injury is present.

It has been observed by several clinicians that deeply jaundiced patients often remain in fairly good condition before operation but that, after surgical relief of the obstruction, intense toxemia develops and is rapidly fatal. The true nature of this condition is difficult to explain. McIndoe and Counseller⁵⁴ have described the marked degree of dilatation of the biliary passages that occurs in cases of complete obstruction, as well as the associated parenchymal lesions. They also suggested that there is a reduction in the portal flow of blood, which may be partly responsible for the hepatic cellular atrophy that is seen in these cases. Consequently, when the obstruction is relieved the pressure in the common bile duct decreases and presumably the stasis of the portal circulation is relieved. Increased blood flow through the liver may wash out into the systemic circulation toxic substances resulting from previous hepatic damage, which are injurious to the kidneys and the capillary walls. Although this explanation of "chole-mia" or "hepatic insufficiency" is theoretical, it deserves consideration for, except in a few cases, the condition cannot be satisfactorily explained on an anatomic basis alone. Crile⁵⁵ and Reid⁵⁶ have gone so far as to recommend gradual decompression of the biliary system in such cases.

EFFECT OF REDUCTION IN THE OXYGEN CONTENT OF THE ARTERIAL BLOOD

One cannot help being impressed with the fact that from both a clinical and an experimental standpoint the liver is somehow concerned with the maintenance of the "internal environment" and, when it fails in this respect, a vicious circle is developed, which is instrumental in producing further disintegration of the hepatic parenchyma as well as changes in the physiologic constants of the living organism. Since the liver is intimately associated with the production of certain

of the constituents of the blood, it is natural to search for changes that might throw some light on the problem from this source.

While working on the problem of pernicious anemia, Rich⁵⁷ noted that there was atrophy of the cells around the central veins of the hepatic lobules, presumably the result of an oxygen deficiency. Both Rich⁵⁷ and MacCallum⁵⁸ found this same type of atrophy in certain types of chronic passive congestion of the liver. Later, Rich and Resnik⁵⁹ reported that atrophy of the cells in the central portion of the hepatic lobule developed if animals were kept in an atmosphere deficient in oxygen. Campbell⁶⁰ and Rosin⁶¹ substantiated this work. These observations made it appear of interest to determine the relationship of oxygen deficiency to other hepatic lesions and its influence on the associated hemorrhagic tendency.

The question naturally arises as to whether anoxemia is ever found in patients with clinical hepatic disease and, if so, what its cause may be and what can be done to correct it. Its occurrence and characteristics have recently been studied by one of us,⁶² and in this work it was found that anoxemia of the anoxic variety was a fairly constant accompaniment of advanced parenchymal hepatic disease. In a study of nine patients who had obstructive jaundice, it was found that the oxygen capacity of the blood ranged from 9 to 20 volumes per cent and that the arterial oxygen saturation was between 79.8 and 95 per cent. Although proof was lacking, there was some evidence to show that the degree of oxygen unsaturation of the arterial blood in general reflected the condition of the patient. When the oxygen saturation of a patient who had hepatic disease was normal, or nearly so, the patient's general state was usually better than average. On the other hand, most of the very low values of oxygen saturation were found in patients who were showing definite signs of hepatic insufficiency. Finally, it was also shown in a few cases that the percentage of oxygen saturation of the arterial blood returned to a normal level as the hepatic lesion regressed. These facts may be of considerable clinical importance in the treatment of hepatic insufficiency with hemorrhage.

Study of the blood of patients whose livers have been damaged reveals that the anoxemia is usually of the anoxic type, as shown by the low percentage of oxygenation of the arterial blood, and that possibly this is attributable to some change in the pulmonary alveoli causing deficient oxygenation of the reduced hemoglobin. This appears to be the proper explanation, since inhalation of oxygen materially increases the oxygen saturation of the arterial blood. Nevertheless, even on repeated examination, constant changes could not be demonstrated in the lungs to which the anoxemia could be attributed, but it is possible that considerable influence might be exerted by minute changes in the alveolar walls, similar to those observed by Rühl⁶³ in experimental animals after shock due to histamine.

In one case the observation that a transfusion of blood appeared to relieve the anoxemia led to further investigation of the problem. In another instance, repeated transfusion not only increased the hemoglobin content and thus the oxygen capacity of the blood but also improved the percentage of oxygenation of arterial blood. These cases are included in the accompanying table.

Of course these beneficial effects may be ascribable to an improvement in the circulation, but they raise the question of whether the hemoglobin produced by a

diseased liver is abnormal. It is known that the liver is intimately associated with the production of hemoglobin, as has been shown by Whipple.⁶⁴ Macrocytic anemia has also been demonstrated repeatedly in cases of hepatic disease and this would lead one to believe that the injured liver is not capable of functioning normally in respect to the production of hemoglobin. This defect is chiefly quantitative, so far as is known, for in man hemoglobin is supposed to be of constant composition.

Investigation of the properties of hemoglobin is difficult, but it is possible to approach the problem by

Chart 1—Oxygen dissociation curves (before and after transfusion) for blood taken from patients with severely damaged livers

two methods (1) spectrophotometric study and (2) study of the dissociation curves. In these cases spectrophotometry revealed no abnormalities, such as the presence of methemoglobin or sulphemoglobin, to explain the observed anoxemia. Up to the present, the dissociation curves of blood of patients with severely damaged livers have shown only a slight variation from the

normal curves for oxyhemoglobin established by Barcroft,⁶⁵ except when there is associated anemia (charts 1 and 2).

In cases complicated by anemia the dissociation curve is somewhat displaced to the right, and in the higher levels of oxygen tension the hemoglobin is not completely saturated, after one or more transfusions the curves have a more nearly normal contour, and because of this fact, and the increased oxygen capacity, the

Chart 2—Oxygen dissociation curves (before and after transfusion) for blood taken from patients with severely damaged livers

blood is theoretically capable of transporting and delivering more oxygen than before. These dissociation curves have been studied under standard conditions of carbon dioxide tension (40 mm) and temperature. They suggest but do not prove that hemoglobin is at least changed by admixture with that of normal blood. In other words, the effect of transfusion on a very anemic patient who has hepatic disease is to improve the blood both quantitatively and qualitatively as a vehicle for the transportation of oxygen, the actual amount of oxygen for delivery to the tissues being thus increased. These changes may be attributable to alterations in the carbon dioxide, electrolyte or protein content of the blood, or to changes in its pH , rather than to changes in the hemoglobin itself, this matter is still under consideration. The importance of these last mentioned factors does not detract from the clinical value of transfusions to patients who have hepatic lesions, for the anoxic and anemic patient apparently receives more benefit from transfusion than can be attributed to the amount of hemoglobin transferred. In these instances, repeated transfusions and inhalation of oxygen are indicated since they relieve the anoxemia, whether it is of the anoxic or of the anemic variety, and thus protect the hepatic parenchyma from the effect of prolonged low oxygen tensions.

Although it is difficult to determine definitely the true cause of anoxemia in cases in which the phenomenon appears, it is quite likely that it has some effect on the progress of the hepatic lesion. It already has been mentioned that reduced oxygen saturation of the arterial blood, produced experimentally, leads to atrophy of the central portion of the hepatic lobule. It may also render the hepatic tissue more vulnerable to influences that could otherwise have been withstood.

COMMENT AND SUMMARY

Several points in this work deserve additional discussion. Anoxemia is not present in every jaundiced patient, but if jaundice exists the degree of unsaturation appears to have some relationship to the general

⁶⁴ Whipple, G. H. Anemia, Liver Function and Hemoglobin Production, Proc. California Acad. Med. 80:102, 1932-1933.

⁶⁵ Barcroft, Joseph. The Respiratory Function of the Blood. Part I. Lessons from High Altitudes. Cambridge University Press, 1925. Part II. Hemoglobin, 1928.

condition of the patient. It is also possible that anoxemia, when associated with hepatic disease, may have a deleterious effect on the progress of the hepatic lesion itself. Consequently, if the anoxemia persists, the liver is likely to be extensively injured and as a result the tendency to bleed will be materially increased.

In order to treat the condition intelligently, it should be borne in mind that the anoxemia may be of two types: (1) anoxic anoxia, which can be corrected by placing the patient in oxygen, and (2) anemic anoxia, which will respond to the transfusion of blood. In the latter instance there is not only an absolute anemia, as is shown by the decrease in the amount of hemoglobin present, but also a relative anoxia, because the ability of the hemoglobin to carry oxygen is diminished in certain cases. It can easily be realized that under the latter circumstances, which appear to exist only in the anemic patient, administration of oxygen alone cannot relieve the situation. On the other hand, marked benefit, for which a theoretical basis has been demonstrated, is apparently derived even from the comparatively small amount of blood given in the transfusion.

Without reference to the mechanism whereby anoxemia is produced in cases of hepatic disease, it is apparent that transfusion has a favorable influence on it in at least three ways: 1. More hemoglobin is supplied, thus increasing the oxygen capacity of the blood. It should be remembered that erythrocytosis is one of the physiologic responses to anoxemia, and that because of a deficient production of hemoglobin this cannot readily occur in the presence of advanced hepatic damage. 2. There is a better saturation of the arterial blood with oxygen after transfusion. This may be the result of an improvement in the general circulation or some change in the character of the blood as a physicochemical system. 3. The functional capacity of hemoglobin may be increased by transfusion. This can be shown by a consideration of the dissociation curves, as is expressed graphically in the accompanying charts. As pointed out, this may involve factors other than the hemoglobin itself: the p_{H} and carbon dioxide content of the blood may be of importance in this respect.

The low mortality among our jaundiced patients in the past year reflects the value of the clinical application of these principles. We feel that the lowered mortality is attributable to the adequate preoperative preparation, the selection of the opportune time for surgical treatment, and the postoperative care as previously outlined. In any case, transfusions of blood have been shown to be of both theoretical and practical value in the control of anoxemia and of the tendency to bleed that is associated with advanced hepatic disease.

ABSTRACT OF DISCUSSION

ON PAPERS OF DR. ZOLLINGER AND DR. JUDD,
SNELL AND HOERNER

DR. F. K. BOLAND, Atlanta, Ga. Dr. Zollinger's inability to reproduce referred pain to the back from gallbladder lesions adds weight to the argument that referred visceral pain usually is the result of inflammation. Mere distention of a viscus does not cause referred pain to any other part. It is stated that inspiratory distress commonly accompanies distention of the gallbladder or extrahepatic ducts. Does inspiratory distress then aid in the differential diagnosis of lesions of the biliary tract from other diseases of the upper part of the abdomen, such as peptic ulcer and pancreatitis? Is inspiratory distress due to back pressure from the biliary tract into the liver which in turn affects the diaphragm? Obstruction of the common duct is productive of more pronounced symptoms than obstruction of other parts of the biliary tract. Vomiting is more apt

to follow distention of the common bile duct than distention of the gallbladder. The recommendation that involuntary retching be added to the other indications for exploration of the common duct brings to mind the seriousness of surgery of the common duct. Cholecystostomy and cholecystectomy may give but little trouble, but one should not attempt operations on the common duct without unusual training and experience. In considering pain in the upper part of the abdomen, with or without vomiting, I think of several patients who suffered from violent attacks diagnosed as angina, when thorough study revealed gallstones, and of one patient whose disease was angina and who was operated on for cholecystitis. The radiation of pain accounts for mistakes in diagnosing these conditions, the mechanism of the radiation being explained by the innervation of the heart and the gallbladder through their mutual complicated connection with the vagus and the autonomic system. Dr. Judd and his co-workers have given what appears to be a reasonable explanation as to how transfusion increases the coagulability of the blood in jaundiced patients. There is no hemostatic agent as effective for hemorrhage as transfused blood. Dextrose is helpful in these cases, because a damaged liver can utilize carbohydrates more rapidly than it can any other nutrient substance. I should like to inquire whether it is better to give pure oxygen or to combine oxygen with 5 or 10 per cent carbon dioxide in order to stimulate deeper inspirations. The fact that oxygen increases the coagulability of the blood emphasizes the importance of giving special attention to maintaining a flat abdomen in these patients, because 90 per cent of the gas accumulating in the intestine is eliminated through the blood and lungs and not through the bowel. Therefore I should think that the less the lungs are crowded with this gas the more oxygen they can absorb.

DR. W. J. MERLE SCOTT, Rochester, N. Y. The explanation by Drs. Judd, Snell and Hoerner of the continuation of bleeding in a patient who has been jaundiced with obstruction over a period of time sounds logical. The height of the jaundice is not the cause of bleeding. I recently operated on a baby with an icterus index of 320, and there wasn't the least tendency in that baby to bleed, from either the muscle or the bed of the spleen. There is one point in regard to damage to liver parenchyma in connection with the explanation that Dr. Judd and his co-authors have given which I have used. After releasing tension on the bile ducts in an obstructive jaundice one has a condition similar to the well known one in the kidneys. Under such circumstances there are hemorrhages in the kidney parenchyma and temporarily, until the circulation of the kidney readjusts itself, there is serious difficulty in that circulation. So I think that also in sudden release of pressure in obstructive jaundice one finds the same type of effect with damage to the circulation of the liver. In two cases with long standing jaundice and very long bleeding time after multiple transfusions and with all the common conservative methods of trying to prepare the patient for operation, it was absolutely impossible to reduce the bleeding time and it was felt that the operative risk was very great. Efforts to perform a cholecystostomy under local anesthesia were successful. A water-tight tube was put in and then the gallbladder was gradually decompressed against water pressure. These patients went through that procedure very well, and it was feasible then to do the larger operation without any difficulty and without bleeding. I think that in the few cases with such extreme jaundice, when there are severe risks from the standpoint of bleeding postoperatively, this method is worth while.

DR. E. S. JUDD, Rochester, Minn. At the clinic, we administered oxygen subcutaneously in several cases, but we found that it was absorbed so rapidly that we were unable to determine that it accomplished anything worth while. We have not tried injection of oxygen in the treatment of jaundiced patients. The sudden relief of pressure in the biliary system is an important consideration. Allowing all the bile to escape at once is unfortunate. When there is deep jaundice and evidence of great pressure in the biliary tract, it is best to perform cholecystostomy and to release the pressure gradually, as Dr. Scott advises. We have followed this plan in a number of cases and feel that it accomplished a great deal.

BLOOD SUGAR CONCENTRATION AND
THE EXTERNAL SECRETION OF
THE PANCREATIC GLANDB P BABKIN, MD, DSc, FRSC.
MONTREAL

The relations between external and internal secretions of the pancreatic gland are far from being clearly understood, although some of the data seem to point to a certain connection between them.¹ The data concerning the activity of the acinous tissue of the pancreas during diabetes are very contradictory. Labbe, Nepveux and Adlersberg² and Gavrila and Parascivisco³ reported a diminution of the enzymatic power of the pancreatic juice activated by intraduodenal introduction of ether in human diabetes. Katsch and von Friedrich⁴ found lower tryptic values in one out of five cases of diabetes. Jones, Castle, Mulholland and Barley⁵ state that in sixty-eight cases of diabetes approximately half the patients showed a diminution in the digestive power of the pancreatic juice. The poor state of nutrition of some of these patients might have played some part in this phenomenon. According to Deusch and Drost,⁶ clinical manifestations of the impaired exocrine function of the pancreas in cases of diabetes mellitus are extremely rare. They may be observed if the diabetes is complicated by pancreatitis, cancer, cysts and the like. In no case of diabetes that they investigated did they find any diminution in the concentration of enzymes in the pancreatic juice.

In experimental animals the results obtained from investigation of the influence of hyperglycemia and hypoglycemia on the pancreatic secretion are likewise conflicting. Savitsch and I,⁷ using dogs with a permanent pancreatic fistula, established that, when a solution of hydrochloric acid to which cane sugar had been added was introduced into the stomach, it stimulated a flow of pancreatic juice having a higher concentration of trypsinogen than the juice obtained when acid alone was introduced. In a series of studies La Barre and Destree⁸ and La Barre,⁹ by means of a method of cross-circulation whereby it was possible to supply blood from one dog (the donor) to the head only of another dog (the recipient), demonstrated that hyperglycemia in the donor increases and hypoglycemia

(insulin, decamethylene diguanidine) diminishes the volume of the pancreatic secretion and the total output of enzymes in the recipient. In order that hyperglycemia might exert a positive effect on the pancreatic secretion, the presence of the thalamic region was essential. On the other hand, Gayet and Guillaumie¹⁰ could observe no increase of the pancreatic secretion when the brain centers were subjected to the influence of hyperglycemic blood.

Collazo and Dobreff¹¹ reported a small but definite increase of pancreatic secretion in the dog after administration of insulin. Deusch and Drost⁶ observed an analogous effect when insulin was administered in man. According to Okada¹² and his co-workers, hypoglycemia stimulates and hyperglycemia inhibits the pancreatic secretion, acting through the vagal centers. On the other hand, Lambert and Hermann,¹³ Penau and Simonnet,¹⁴ Chiray, Lebon and Gozlan,¹⁵ and Fonseca and Carvalho¹⁶ deny the secretagogue effect of insulin on the pancreas. La Barre and Destree⁸ noted a marked inhibition of the pancreatic secretion in dogs after administration of insulin.

This unsatisfactory state of affairs induced us to reinvestigate experimentally some aspects of the complicated problem of the pancreatic function during disturbances of carbohydrate metabolism.

RESULTS

During the last few years we have become interested in the effect of the blood sugar concentration on the secretory activity of the digestive glands, and especially on the output of enzymes from the pancreas in hyperglycemia and hypoglycemia. Experiments were performed on dogs and cats, but chiefly on rabbits. The last-mentioned animal offers great advantages for this type of experiment, since its pancreatic gland secretes continuously and spontaneously.¹⁷ Different anesthetics were used, amytal or pentobarbital sodium being preferred as having the least effect on the blood sugar concentration. In some experiments the spinal cord was cut below the medulla after brief ether anesthetization. The pancreatic duct was cannulated, the adrenals were removed or left intact, according to the requirements of the particular experiment. The concentration of only one of the three principal enzymes of the pancreatic juice was determined, since these enzymes are secreted in parallel concentration by the pancreatic gland in the dog,¹⁸ in man¹⁹ and in the rabbit.²⁰

The chief results obtained by us are as follows.

Miss C O Hebb established that in the rabbit there is a close parallelism between the degree of glycemia and the concentration of enzymes in the pancreatic juice. The rise or fall of the blood sugar concentration, in spite of the fact that the secretion of pancreatic juice remains very often constant in volume, is accom-

panied by a rise or fall of the enzymatic activity of the juice. This is evident from several types of experiments. If the blood sugar level is kept constant during the experiment, there is no fall in the concentration of enzymes, e. g., in the case of urethane (ethyl carbamate) anesthesia, if the usual postoperative hyperglycemia gradually diminishes, there is also a slow fall in the enzyme concentration, if the fall of the blood sugar concentration is arrested and it goes up (owing to struggling of the animal, administration of ether and the like), the enzymatic activity of the pancreatic juice remains on the same level or increases.

That it is the concentration of dextrose in the blood that regulates the output of pancreatic enzymes was shown by Miss Hebb in experiments in which dextrose (usually 5 cc of 20 per cent dextrose solution) was administered intravenously. Without a single exception

fact, in many experiments the enzymatic activity of the pancreatic juice was diminished after injection of these substances.

We subjected to thorough analysis the fact of the increased output of enzymes by the pancreas under the influence of dextrose.

The possible excitation of the adrenal secretion by an excess of dextrose in the blood and consequent stimulation of the pancreatic secretion was excluded in the experiments on doubly adrenalectomized animals carried out by Dr. Baxter²¹ and Miss Hebb.

Next comes the problem of the passage of dextrose through the acinous cells and the possibly favorable effect thereby produced on the enzymatic activity of the pancreatic juice. The majority of the experimental and clinical investigators are inclined to think that neither after the introduction of a large amount of dextrose into the blood of experimental animals nor in cases of severe diabetes does dextrose appear in the saliva. But, as far as we could ascertain, nothing was known concerning the behavior of the pancreatic gland under similar circumstances.

Miss Hebb clearly demonstrated that the pancreatic acini are much more readily permeable to dextrose than are the secretory cells of the salivary glands. She determined the reducing substances by the Hagedorn-Jensen method before and after yeast fermentation of the protein-free filtrate of pancreatic juice obtained from rabbits, dogs and cats under anesthetics. Dextrose was recovered from the pancreatic juice of rabbits in amounts of from 10 to 50 mg per hundred cubic centimeters, when the blood sugar concentration varied between 200 and 300 mg. Intravenous injection of dextrose greatly raised the previous values. When, after dextrose administration, the hyperglycemia was 385 mg per hundred cubic centimeters and over, the concentration of dextrose in the pancreatic juice rose to 100 mg and higher. Analogous relations were found in the case of the pancreatic juice of dogs and cats secreting under the influence of secretin. When the concentration of the blood sugar was moderate, the pancreatic juice contained sometimes traces, sometimes as much as a few milligrams per hundred cubic centimeters of sugar. These values rose greatly (i. e., as high as 70 or 80 mg per hundred cubic centimeters) after the intravenous administration of dextrose. The permeability of the pancreatic cells to dextrose was not impaired by atropinization of the animal.

The first step in the analysis of the effect of the blood sugar concentration on the pancreatic secretion was to find out how the increased concentration of dextrose in the pancreatic juice may affect its enzymatic function. It was thought that the increase of the digestive power of the pancreatic juice during hyperglycemia might possibly be due to the favorable action of dextrose, present in the pancreatic juice, on its enzymatic functions. This hypothesis was disproved with regard to the lipolytic and the tryptic activity of the pancreatic juice. The addition of dextrose in various amounts (0.1 cc of 0.05, 0.1 or 0.2 per cent solutions) to the pancreatic juice did not produce any beneficial effect on the action of lipase or trypsin. No experiments were performed with amylase, but Clark and Edwards²² reported that the amylolytic activity of malt diastase was not affected by weak concentrations of dextrose and was inhibited by stronger concentrations.

† In this and the following table, corrected lipase units means the lipolytic power of the pancreatic juice when the dilution factor is taken into consideration. This is calculated according to the formula: $\frac{\text{volume for 1 hour}}{1 \text{ cc.}} \times \text{lipase units in 0.1 cc.}$

the rise in the blood sugar level increased the concentration of enzymes in the pancreatic juice (table 1). In many experiments this occurred when there was no change whatever in the rate of secretion of the juice. From this it would seem that under certain circumstances dextrose may increase the output of organic material and enzymes from the glandular cells without affecting greatly the rate of secretion of the fluid parts of the juice.

The effect of dextrose on the secretory function of the pancreatic gland was found to be specific. Since the intravenous introduction of concentrated solutions of dextrose may change the osmotic pressure of the body and tissue fluids, it was thought that it might also affect in some way the secretory function of the pancreas. However, control experiments with intravenous administration of isosmotic solutions of sodium chloride, sodium bicarbonate and cane sugar did not produce any effect comparable to the effect of dextrose on the function of the acinous cells. As a matter of

The conclusion to be drawn from these experiments is that the increased enzymatic activity of the pancreatic juice in hyperglycemic animals does not depend on the presence of dextrose in the secretion. Therefore the changes in the enzyme concentration of the pancreatic juice after administration of dextrose are due to some processes occurring in the body, probably in the pancreas itself. Since the parasympathetic nervous system, as is well known,²³ regulates the output of enzymes from the pancreatic gland, the effect of atropine was tested. After the administration of atropine the concentration of enzymes usually fell slightly. The injection of massive doses of dextrose together with atropinization did not increase the concentration of enzymes in the pancreatic juice and even failed to prevent its customary fall (table 2). The latter fact is further evidence that the presence of dextrose in the juice, the passage of which substance through the acinous cells is not prevented by atropine, does not increase its enzymatic activity. Therefore it seems justifiable to conclude that dextrose stimulates that function of the acinous cells of the pancreas which is concerned with supplying enzymes to the juice, and that it acts through the medium of the parasympathetic nervous system. Since this effect was observed in animals with the vagi cut, it appears to be mainly of a peripheral nature. However, special experiments are needed to determine whether the central nervous system participates in this phenomenon or not.

The effect of hypoglycemia was studied in our laboratory some time ago by Dr. S. G. Baxter.²¹ After the work of Miss Hebb, his data now appear in a somewhat different light. Dr. Baxter established that the hypoglycemic state of the blood provoked by insulin diminishes the discharge of enzymes by the pancreatic gland in the rabbit. Usually the volume of the pancreatic secretion during hypoglycemia also decreased, but in some experiments this decrease was very insignificant or entirely absent. Nevertheless in all cases the tryptic power of the juice gradually diminished with the fall of the blood sugar concentration. To avoid the increased output of epinephrine during hypoglycemia,²⁴ in most of Baxter's experiments the adrenals were removed or their veins were tied. The effect of hypoglycemia on the discharge of pancreatic enzymes depends on the integrity of the vagi. If both vagi were sectioned, there was an absence of any significant fall in the enzymatic power of the pancreatic juice during insulin hypoglycemia. The volume of the secretion, however, was very often diminished.

Intravenous administration of dextrose in massive doses to hypoglycemic animals with the vagi intact as well as after section of the vagi, restored the flow of the pancreatic juice if it was inhibited and greatly increased the concentration of enzymes in the pancreatic juice. Moreover, the beneficial effect of dextrose did not depend on the integrity of the sympathetic nerve supply to the pancreatic gland because it was observed in vagotomized and splanchnicotomized animals.

COMMENT

These investigations firmly establish certain facts concerning the interrelations between the blood sugar concentration and the exocrine activity of the pan-

creatic gland. In the present unsatisfactory state of our knowledge of the intimate processes taking place in a secreting gland, however, the interpretation of these data is very difficult.

The first fact which must be taken into consideration is that the blood sugar concentration affects separately the "secretory" and "trophic" functions (so designated by R. Heidenham) of the pancreas. It is the latter function (i.e., the discharge of organic material and enzymes by the glandular cells) that is always stimulated by the excess of dextrose in the blood. The changes in the volume of the secretion are not so constant. Our experiments showed that hyperglycemia influences the "trophic" function of the pancreas always, and its secretory function sometimes, by direct action on the gland itself. In the case of the "trophic" function it acts presumably through the endings of the parasympathetic nerve. However, the possibility of the influence of the central nervous system cannot be

TABLE 2—Experiment Showing that Massive Doses of Dextrose After Administration of Atropine Did Not Increase Concentration of Enzymes in Pancreatic Juice *

excluded. On the other hand, hypoglycemia exerts its effect through the central nervous system. The inhibitory impulses to the acinous cells are discharged along the vagus nerves. From their nature, they may be called "trophic-inhibitory" or "negative-trophic" impulses.

All these facts are indicative of a relationship between the blood sugar level and some metabolic processes taking place in the secretory cells during their activity. There are already indications that the carbohydrates play an extremely important part in the processes of secretion. Anrep and Cannan²⁵ found that stimulation of the chorda tympani or pilocarpine administration increases the consumption of blood sugar by the submaxillary gland of a dog. Hober and Ferrari²⁶ found that the metabolism of the active submaxillary gland is analogous to that of working muscle. The secretory work depends on carbohydrates and on an organic phosphoric compound present in the glandular tissue and is to a certain degree independent

of oxygen supply. During stimulation of the chorda tympani the concentration of lactic acid and of phosphoric acid in the blood of the glandular vein greatly increases. Still, Bennett and Scott²⁷ showed that in a dog the secretion of the pancreatic juice activated by highly purified secretin is accompanied by an increased consumption of oxygen. The average respiratory quotient of the resting pancreas is 0.79. During the secretory activity of the gland the average respiratory quotient (extra respiratory quotient) was found to be 1.05. The concentration of lactic acid in the venous blood collected from an active pancreas was increased. All this suggests that the carbohydrate metabolism is increased during the secretory activity of the organ. Undoubtedly further work is necessary in order that the part played by the secretory nerves in the metabolism of a secretory gland may be understood.

What is the explanation of the variety of results obtained in different cases of diabetes mellitus in human beings in relation to the pancreatic secretion? The discrepancy in the determination of the volume of the pancreatic secretion and the enzyme concentration is undoubtedly due in some degree to the unsatisfactory methods employed in obtaining the pancreatic juice from human subjects. Another cause may be the different state of the acinous cells in various cases of diabetes. It is legitimate to suppose that the degree of hyperglycemia in a given case of diabetes will determine the amount of zymogen granules stored in the pancreatic cells and hence the concentration of enzymes in the juice.

SUMMARY

The existence of a close relationship between the blood sugar level and the secretory processes of the pancreatic gland has been established. Hyperglycemia always increases the output of enzymes from the acinous cells and in certain cases increases the volume of the secretion. The effect of hyperglycemia is chiefly peripheral, the parasympathetic nervous system presumably participating in this. Hypoglycemia produced by the administration of insulin lowers the concentration of enzymes in the pancreatic juice. After section of the vagus nerves this effect disappears.

ABSTRACT OF DISCUSSION

DR A. H. AARON, Buffalo. I have repeatedly determined the lipase and amylase concentration in the B fraction of the duodenal contents in a single individual with achlorhydria. Feeling that these results are as near standardized as can be obtained by usual intubation, I repeated Dr Babkin's experiment as nearly as possible in this individual. Hyperglycemia was produced and maintained during the drainage of the B fraction by repeated intravenous injections of dextrose. At no time during this experiment did the concentration of ferments increase in the duodenal contents. Determinations for amylase were performed according to Ivy's modification of Willstätter's method, and lipase was determined by the method of Cherry and Crandall.

DR B. P. BABKIN, Montreal. The methods of collection of pancreatic juice in man are unsatisfactory. What one gets from a duodenum is three or four juices, and besides that one gets fifteen enzymes and activators, so, really, I think that the clinicians will have to find better methods to get the pancreatic juice less contaminated with other secretions, in which it will be possible to determine with a reasonable accuracy the relative concentration of the three principal enzymes.

ANESTHESIA FOR THYROCARDIAC PATIENTS

L. F. SISE, M.D.
BOSTON

A thyrocardiac patient is one having thyroid toxicity and significant heart disease. For the purposes of making a study of the end results, significant heart disease has been taken to be (1) auricular fibrillation or flutter, or (2) congestive heart failure.¹ Many most serious cases of heart disease, however, which might appear to be quite dangerous for the administration of an anesthetic, do not fall within this group. For this reason it has seemed best in studying the effect of anesthesia to include in this group not only the aforementioned heart conditions but also cases of coronary disease, angina pectoris, and the two most serious valvular lesions, mitral stenosis and aortic regurgitation. The question of diagnosis will not be considered. All diagnoses have been made by the medical department of the Lahey Clinic. No doubtful diagnoses have been considered, but when a definite diagnosis was made by the medical department this diagnosis has been taken as final.

Our early operations were done with local anesthesia. After a comparatively small series of cases this was gradually replaced by nitrous oxide, and a considerable series of cases was done with this gas. In 1924, following the introduction of ethylene, a change was made to this drug, and the resulting series of cases is by far the largest. Following the work of Waters with cyclopropane we made still another change and now do these toxic heart cases largely under cyclopropane.

In the course of this considerable series of cases under these various anesthetics it is only natural that certain opinions and conclusions should have been formed concerning the value and limitations of these various anesthetics.

Local anesthesia is favored by many and has considerable value in lack of toxicity and in that it does not itself place an appreciable load on the heart. We have found, however, that with these cases in actual practice it has certain definite drawbacks. 1 These toxic patients are nervous and excitable and often react very poorly to the conscious state during operation. We believe that on this account we have seen venous congestion very definitely increase during operative procedures. Of course, preliminary medication helps considerably, but its effect varies so much between different individuals that its results are uncertain and not to be depended on. 2 Anesthesia is inadequate in many cases. The points where it is apt to be inadequate are during elevation of the lateral lobes and during extraction of extensions below the clavicle. Of course a cervical plexus block will take care of most of these points quite well, but the administration of the block itself is too much of an ordeal for these patients to endure. For these two reasons we have found it necessary to augment local anesthesia with a gas anesthetic in the majority of instances. 3 Under local anesthesia the surgeon is more restricted. He does not have the freedom for rapid manipulation and wide exposure that he has under a general anesthetic. For these three

From the Lahey Clinic.
Read before the Section on Miscellaneous Topics, Session on Anesthesia, at the Eighty-Sixth Annual Session of the American Medical Association, Atlantic City, N. J., June 12, 1935.

27. Still, E. U., Bennett, A. L., and Scott, V. B. *Am. J. Physiol.* 106: 509 (Dec.) 1933.

reasons we believe that in these cases local anesthesia is inferior to certain forms of general anesthesia. It was abandoned quite early in our work with these cases, so that our total experience with it has been comparatively small.

Nitrous oxide is of value in that it does not of itself have appreciable toxic action or place an increased load on the heart. It is, however, inevitably accompanied by at least some degree of anoxemia. This anoxemia increases the load on the heart and at the same time, by decreasing the oxygen supply to the heart muscle, renders the heart less able to carry even the same load. The situation is still further complicated by the fact that these thyrotoxic individuals require more than the normal amount of oxygen and are often somewhat resistant to anesthesia. In addition, nitrous oxide is a comparatively weak anesthetic and does not satisfactorily suppress certain reflex effects. It often happens that considerable manipulation of the trachea is necessary in the course of the operation and that this may produce a strong reflex tendency to cough and laryngeal spasm. If these effects do take place, the resulting anoxemia may be much worse than if a deeper degree of anesthesia had been maintained in the first place. The anesthetist is thus in a quandary as to which of the two courses open to him is the less bad—the light anesthesia, which may at any moment result in spasm and deep anoxemia, or the deeper anesthesia, which carries anoxemia from the start. The situation is bad enough in patients with normal hearts, though here the anesthetist of reasonable skill and experience has sufficient warning of trouble to enable him to bring the patient safely through. But when, as occasionally happens in these cases, the myocardium is seriously damaged and incapacitated, this warning may be reduced practically to zero.

The inevitable tragedy that results has occurred twice in my own experience. These two cases have been reported elsewhere in detail,² but the second case has such value as a warning to others that it is worth mentioning again here. After approximately 2,000 thyroid cases under nitrous oxide, this second fatality occurred just eight days after the first one. With the first case thus fresh in mind, I was naturally particularly cautious and alert. Yet, with everything apparently going smoothly and safely, cessation of heart action occurred with an abruptness that appeared absolute.

Our series of thyroid operations under nitrous oxide has been comparatively large and in many respects has been reasonably satisfactory. Nevertheless, in these toxic heart cases, both from theoretical considerations and from practical experience, nitrous oxide appears to be fraught with danger. For this reason and because it has often been extolled as one of the safest anesthetics, I should like to give as my emphatic opinion that in these cases it is a dangerous anesthetic.

It must further be said, however, that the danger lies not in the nitrous oxide itself but in the anoxemia that accompanies it. If one uses preliminary medication or an adjuvant in sufficient amount to avoid this anoxemia, this particular danger is removed. Toxicity or depression may be added, but these appear to be lesser evils than anoxemia. I believe that in cases of damaged myocardium the latter should be avoided absolutely.

Ethylene has for these cases two important advantages over nitrous oxide. It can be used with a considerably larger amount of oxygen and it suppresses much more satisfactorily the reflex effects. The great advantage of these two points will be evident from the discussion of nitrous oxide. Its toxic action appears to be minimum. Our series under ethylene is the largest of any anesthetic and does not include any case in which death appeared to be the direct result of the anesthetic. A small amount of anoxemia frequently accompanies it. This is not enough to be dangerous to the normal heart but should be avoided with the damaged organ. For this purpose sufficient oxygen may be added to overcome the anoxemia, and the desired depth of anesthesia maintained by the addition of a small amount of ether. Of late we have often used cyclopropane as the adjuvant. Either combination makes a very satisfactory anesthetic for these cases. I am unable now to say which is the better.

Cyclopropane appears desirable for these cases because of the unusually large amount of oxygen that can be used with it. Experimental evidence indicates toxic action on the heart in the higher concentrations. Whether in the lower concentrations used in anesthesia this action is of sufficient degree to be of moment or whether it is even present at all is not now apparent. Whatever the reason, certainly there is a marked difference in the immediate postoperative recovery of patients in whom different depths of anesthesia have been given. Those who have been given a minimal degree of anesthesia have had surprisingly few after-effects, while those cases in which a considerable depth has been accomplished often show considerable depression. Reflex effects are controlled quite well even by light degrees of anesthesia.

Not only is the complete avoidance of anoxemia under cyclopropane of advantage but it is even possible that the more than normal percentage of oxygen under this anesthesia may be of further additional value in itself. This possibility is indicated by the work of Barach,³ who showed that in heart failure, especially of the nonrheumatic type, the employment of 50 per cent oxygen enables many patients to regain their compensation when other measures have failed. This indicates the possibility that abnormally high oxygen during anesthesia may aid the damaged myocardium to handle the strain.

Regardless of the particular drug used for anesthesia, a few general conclusions are justified.

1. Anoxemia is to be avoided especially in those cases presenting a damaged myocardium. This has already been sufficiently discussed but needs to be stressed.

2. Obstruction to respiration is to be avoided. Not only does this tend to the production of anoxemia but the labored breathing which it engenders is just so much extra exertion to the patient and a bother to the surgeon in his work. An efficient airway should be used as a routine. In cases in which compression of the trachea is shown by x-rays it is advisable to use intratracheal anesthesia. Cyclopropane is an excellent anesthetic for the insertion of the tube, but in the really bad risk cases it is better to avoid the considerable depth necessary for this procedure by using local anesthesia of the larynx. This may easily be obtained by spraying 10 per cent cocaine through an airway under light gas anesthesia.

* Grade 1 is a good risk, grade 2 a fair risk, grade 3 dangerous and grade 4 a probable fatality Almost two thirds are classed as dangerous risks

cases in which the soda lime had become exhausted and had been replaced during the operation by fresh soda lime, the beneficial effects of this procedure have been most strikingly demonstrated

5 The depth of anesthesia should be nicely adjusted so that, while reflex effects are controlled, the dangers of anoxemia and the depressing or toxic effects of more than minimal depth are avoided

So important are these points that I believe the proper conduct of the anesthesia in these respects is much more important than any niceties in the choice of the particular anesthetic agent

STATISTICS

In order to make certain facts about these cases more clear and definite I have analyzed and tabulated the last 100 cases In most respects the tables are self explanatory, but they can be clarified by comment in some instances The risks are graded from 1 to 4, 1 being a good risk, 2 a fair risk, 3 a dangerous risk, and 4 a probable fatality These risks are all graded by the anesthetist and are recorded on the chart before operation When one notes from the tables that almost two thirds of these cases were graded as dangerous and that just about two thirds of the patients were 50 years of age or over, and when one notes the various

heart conditions and realizes that, in addition, all these patients were suffering from thyroid toxicity, a fairly clear idea is had that this group as a whole was a decidedly dangerous risk The serious condition of this group is also indicated in table 5, in which it is seen that multiple stage operations were thought necessary in all but thirteen cases

COMPLICATIONS AND DEATHS

In considering the complications and deaths, one encounters the usual difficulty in determining how much is due to the anesthetic and how much has nothing whatever to do with it

One is struck at once by the fact that every one of these patients had auricular fibrillation and that every patient having a complication had, in addition, congestive heart failure Such cases are particularly prone to the occurrence of emboli Emboli appear to account for complication 3, temporary hemiplegia, and death 2, sudden death Complication 1, excessively high pulse rate during anesthesia, was probably due to toxicity and the initial heart condition Whether any other anesthetic would have proved better is impossible to

* Thirty six patients had more than one

say Complication 2, spontaneous pneumothorax, was unusual One cannot help wondering whether the respiratory obstruction during operation, with probable labored breathing, did not have some causal relationship Against this view is the large number of cases presenting similar obstruction but without this compli

cation, which we had in this clinic before our free use of intratracheal anesthesia. No relation to the anesthetic was indicated in complications 4 and 5.

The relation of the anesthetic to the two deaths from thyroid storm must remain an unsolved problem. Thyroid storm is often caused by or accompanied by pneumonia and appears to be related in some way to liver failure, as suggested by Dr. Lahey. Both of these were present in death 1. In this case ethylene-ether was used, though but a small amount of ether was given. In the other case, ethylene was used. This drug is not one that is generally believed to have any tendency to the production of either pneumonia or liver failure. In fact, the causes entering into the production of postoperative pneumonia are still obscure in many respects. On the whole it seems probable that the cause of postoperative thyroid storm lies in the preoperative condition of the patient, the amount of surgery done, and the conduct of the anesthesia, rather than in the particular anesthetic agent used.

The operative mortality of 3 per cent here recorded is not far from that of 4.25 per cent reported by Lahey and Hurxthal in reviewing 300 of these cases in 1933.

COMPLICATIONS

CASE 1—A woman, aged 53, severely toxic, whose heart was greatly enlarged, had auricular fibrillation and congestive heart failure. On coming to the operating room the pulse became very rapid. She was given cyclopropane, and the pulse rose still further to 200. The operation, therefore, was limited to ligation of the superior thyroid poles. As it was felt that apprehension played a prominent part in the rapid pulse at this operation, at the next stage she was given tribrom-ethanol in her room before coming to the operating suite, and this was followed by cyclopropane for the operative procedure. Nevertheless the pulse rose just the same, in fact reaching this time a high of 215. It was felt best, therefore, by the time the muscles had been cut to conclude the operation. She recovered without further complication.

CASE 2—A man, aged 45, very toxic, with auricular fibrillation and congestive failure, had marked tracheal obstruction during operation. (Use of the intratracheal method would have been preferable.) Ethylene-cyclopropane anesthesia was administered. At two and three-quarters hours after the operation there was sudden dyspnea and cyanosis. Diagnosis was made of spontaneous pneumothorax, and 1,100 cc. of air was withdrawn. Next day 900 cc. more was withdrawn and the patient thereafter made an uninterrupted recovery. This patient eventually made a most remarkable improvement over his pre-operative condition.

CASE 3—A woman, aged 49, with auricular fibrillation and congestive failure, on the second day had a sudden hemiplegia. This was considered at the time to be embolic in nature. Recovery was rapid and complete.

CASE 4—A woman, aged 49, mildly toxic with auricular fibrillation and congestive heart failure, in early convalescence developed hydrothorax. This was felt to be due to the giving of too large an amount of intravenous fluids. These were stopped and she made a prompt recovery.

CASE 5—A man aged 39 with auricular fibrillation and congestive failure, during convalescence had an acute attack of dyspnea and palpitation from which he recovered spontaneously.

DEATHS

CASE 1—A man, aged 67, was operated on in two stages, each under ethylene-ether. At the first stage he had auricular fibrillation and congestive failure but made an uneventful convalescence. At the second stage he still had fibrillation but had recovered from the failure. This operation was much more severe than the first stage, as he had an intrathoracic extension on the left the size of a small grapefruit, which descended into the chest and crossed over the trachea to the right side, and which was extricated from the chest only with considerable difficulty. He did well for two days but then had thyroid

storm, cyanosis, jaundice and bronchopneumonia, and died. Just which of these complications was primary and which secondary is not clear, but the postmortem examination, which was allowed for the chest only, gave bronchopneumonia as the only cause of death.

CASE 2—A woman aged 39, had auricular fibrillation. She had an uneventful operation and convalescence till the fifth day, when she was given 21 grains (1.4 Gm.) of quinidine to control the fibrillation and died very suddenly. Cerebral embolism was thought to be the probable cause of death.

CASE 3—A man aged 67, had auricular fibrillation and congestive failure and a very large intrathoracic goiter. His condition was very critical, but operation appeared to be only hope. He died in two days of thyroid storm.

SUMMARY

The ordinary definition of a thyrocardiac condition is enlarged to include coronary disease, angina, mitral stenosis and aortic regurgitation.

Local anesthesia is inferior to the gases because (1) these patients are unusually nervous, (2) anesthesia is inadequate (unless block is used), and (3) the surgeon is restricted.

Of the gases, nitrous oxide is dangerous on account of anoxemia, unless much premedication or an adjuvant is used. The best anesthetics are ethylene, cyclopropane, ethylene-cyclopropane or ethylene-ether. A nice choice between these is less important than the proper conduct of anesthesia. This should include (1) avoidance of anoxemia, (2) avoidance of obstruction, (3) liberal premedication, (4) minimal rebreathing, and (5) nicely adjusted depth of anesthesia.

In our last 100 cases there were five complications and three deaths.

605 Commonwealth Avenue

ABSTRACT OF DISCUSSION

DR. ANSEL M. CAINE, New Orleans. New Orleans and its surgical territory have few toxic goiters when compared to Boston and the Middle West. We do have them, however, and nearly every toxic thyroid is a cardiac case if of any standing. I agree with Dr. Sise in his conclusions regarding oxygenation. I think we should take it even further than is done in his discussion, that is, treat the case preoperatively and postoperatively with oxygen. Barach has used it to great advantage. The pulse rate and heart action are greatly improved. Oxygen is not discontinued even on the way to the surgery and is commenced again before the patient is returned to bed. Barach again emphasizes this at the oxygen therapy exhibit. Cyclopropane permits oxygen therapy during anesthesia. Too much cannot be said of the importance of an open airway. The surest way to secure this is with an endotracheal tube. Spraying the throat with a 10 per cent solution of cocaine to abolish reflexes is not without danger, unless the patient's tolerance to cocaine is known. No one with whom I have talked here seems to have had trouble. My fifth patient (not thyrocardiac) went into convulsions. These were promptly relieved by intravenous injections of amytal, the temperature, which had reached 103 F., returned to normal in two hours. I saw a death some years ago from swabbing the throat with a 20 per cent solution of cocaine to abolish reflexes for local tonsillectomy. The temperature rose to 108 F. plus. The same week another death took place in Selma, Ala., under similar circumstances. Therefore, the danger is real and not fancied. Premedication, to avoid suspicion on the part of the patient as to the contemplated time of the operation, can be accomplished by giving capsules for 'treatment' at a routine time for several days ahead then duplicating the capsules but changing the contents on the day of operation. The hypodermic injection is given after the patient is asleep from the capsules.

DR. MILTON J. RAISEBECK, New York. I heartily endorse Dr. Sise's paper. The factors that hamper the heart are, first and foremost, lack of oxygen. In following cases to the operat-

ing room I have come to the opinion that this problem of lack of oxygen cannot be solved in many cases with nitrous oxide except in the hands of an exceptionally skilful anesthetist. Our knowledge of cyclopropane is limited, it may have some action on the heart, but the large amount of oxygen one is able to give with it and the fact that relaxation is secured apparently with light dosage would appear to give it an advantage over other anesthetic agents, although ethylene has been the one with which I have had the most experience. The second source of danger for the heart is the production of spasm or any violent muscular effort. The type of heart that cannot stand mechanical stress is chiefly the older arteriosclerotic heart, one with a history of anginal pain or coronary disease. The anesthetic that produces rapid and easy relaxation would thus have an advantage. The third factor that may increase the cardiac burden is a rise in blood pressure, but I do not feel that this is as important as the others. I have observed a rise in blood pressure during operation to quite a considerable height without affecting the heart adversely. Of course a rise in blood pressure may be associated with lack of oxygen and then the effect is certainly harmful. The problem is up to the anesthetist, and it depends on his skill rather than on the qualities of the agent itself. The bad risks that I have observed all showed auricular fibrillation and/or congestive failure. In my experience fibrillation is an added risk but not a great one, whereas congestive failure is a serious factor. If the patient has to go to operation with moisture at the lung bases and with enlargement of the liver, or with edema anywhere, he is a very bad risk. There is one hint that may be useful. Incipient failure may be detected in the absence of physical signs by determining the circulation time. If decholin is injected in the vein at the elbow, the patient will report a bitter taste normally within eighteen seconds. Gluside can be used in a similar way and is somewhat cheaper. If the circulation time, as revealed by this test, is markedly slow even without objective evidence of heart failure, the patient is going to be more than usually sensitive to the lack of oxygen, mechanical stress or any of the other hazards of anesthesia and will therefore demand special attention.

DR S C WIGGIN, Boston. I agree with everything that Dr Sise has said about nitrous oxide in thyrocardiac and thyroid cases in general. I am glad that Dr Sise modified the first statement that nitrous oxide is dangerous in thyrocardiac patients with the statement that it can be used if sufficient premedication and an adjuvant are administered. At the Faulkner Hospital we have had about 150 thyroid patients in the past two years, including more recently a small percentage of thyrocardiac patients with cardiac deficiency. I have limited the use of morphine in these cases because I find that they do not need the total dose, the larger doses which the hyperthyroid or the tumors of the thyroid need. In the operating room, instead of starting with gas-oxygen, I oxygenate the patient first with plenty of oxygen and then I am able to put him to sleep with a low concentration of nitrous oxide. The surgeon thoroughly infiltrates the thyroid region with 1 per cent solution of procaine hydrochloride, which enables me to use a very light concentration of nitrous oxide and oxygen, probably more than a deep sleep. In cases of auricular fibrillation I have noticed the blood pressure come down from a high level. One patient started with a pressure of 190, in the course of about twenty minutes it was down to 120 and her pulse, starting at 120, came down to 80 and the clinical course ran level to the end of the operation. If nitrous oxide is used discreetly in these cases, it is of value.

Eugenics—Sir Francis Galton, the founder of the science, was also the founder of the first modern eugenics society "The Eugenics Education Society of Great Britain." In the leadership of this society, Sir Francis Galton was succeeded by Major Leonard Darwin. By 1912 the scientific advance of eugenics in many different countries seemed to warrant an international congress. Accordingly, the first International Congress of Eugenics duly assembled in London in July 1912—Laughlin, H. H. Historical Background of the Third International Congress of Eugenics. A Decade of Progress in Eugenics, Baltimore, Williams & Wilkins Company, 1934.

FACTORS CAUSING BRONCHIECTASIS

THEIR CLINICAL APPLICATION TO DIAGNOSIS AND TREATMENT

W P WARNER, M.B., F.R.C.P (C.)
TORONTO, ONT

Bronchiectasis may be defined as a condition in which the bronchial tubes are dilated beyond their normal size. The pathologic process present practically always produces symptoms, the commonest being chronic cough and sputum. Most cases of bronchiectasis were diagnosed "chronic bronchitis" until 1922, when Sicard and Forestier¹ discovered the usefulness of iodized oil, which was radiopaque and could readily be injected into the bronchial tree without danger, and bronchial dilatation could be diagnosed with certainty. It is since then that our knowledge of this disease has progressed markedly. Recent studies have shown more clearly the pathologic process involved in bronchiectasis. This work will be reviewed and the interpretation of signs and symptoms on this pathologic basis will be discussed, as well as the rationale of treatment.

ETIOLOGY OF ACQUIRED BRONCHIECTASIS

In a recent survey of 110 cases of bronchiectasis, which have been thoroughly studied and followed for varying periods of time up to eight years, it was found that the bronchiectasis began with a known illness in 59 per cent pneumonia, 30 per cent, lung abscess, 12 per cent, influenza, 5 per cent, whooping cough, 4 per cent, "acute bronchitis," 3 per cent, measles, 2 per cent, bronchogenic carcinoma, 2 per cent, foreign body, 1 per cent. In 41 per cent of the cases the onset was insidious, there being no history of any acute respiratory infection immediately preceding the onset of bronchiectasis. However, the frequency of an acute respiratory disease preceding the bronchiectasis and the character of the general and local symptoms during the course of the disease strongly suggest infection as the important etiologic factor.

The next question is What tissue in the lung is primarily affected by this infection? The hypothesis of Andral² and Stokes³ was that the primary cause of bronchiectasis is a weakening of the bronchial wall with subsequent dilatation. Later, Corrigan⁴ and Hamilton⁵ were the first to advance the theory that in bronchiectasis the primary fault is in the parenchyma of the lung, the bronchi dilating secondarily to fibrosis in the parenchyma and to pleural adhesions.

Recent work has done much to determine which of these theories is correct. Warner and Graham⁶ have demonstrated from observations on bronchiectatic lobes at operation and after removal (lobectomy) that bronchiectasis may occur without either fibrosis of the lung or pleural adhesions being present. Further evidence in support of this fact was obtained by the same investigators when they observed lobar atelectatic bronchiectasis appear in such a short time that the more chronic process of fibrosis could not account for it. Having

excluded fibrosis of the lung and pleural adhesions as necessary factors in the production of bronchiectasis, they turned to a consideration of a possible weakening of the bronchial wall. From the examination of surgically removed bronchiectatic lobes, Robinson⁷ has shown that the most marked and consistent pathologic finding is chronic inflammation of the bronchial wall, often with complete destruction of the muscle and elastic tissue. Greey⁸ made a bacteriologic study of the same material and found a variety of organisms present. He concluded that no specific organism produces the infection which causes damage to the bronchial wall. It is my opinion, therefore, that the initial fault in bronchiectasis is damage and subsequent weakening of the bronchial wall, probably caused by a nonspecific infection.

Forces Causing Physiologic Bronchial Dilatation—Given a weakened bronchial wall with loss of elastic and muscle tissue as the primary fault in bronchiectasis, there must be some mechanical reason for the bronchus to become dilated. There have been many explanations offered for this bronchial dilatation, but I believe that there is a simple and adequate explanation.

Physiologic bronchial dilatation has been described by Macklin⁹ and others. By bronchoscopic examination and by roentgen examination with iodized oil in the bronchial tree it may be seen that a normal bronchus becomes dilated during inspiration and narrowed on expiration. This physiologic dilatation on inspiration is brought about by forces that are the chief cause of permanent or pathologic dilatation occurring in bronchiectasis. These forces are, first, the direct pull of the expanding thorax on the bronchi, transmitted through the parenchyma, second, the difference in pressure between that in the lumen of the bronchus and that outside its wall occurring on inspiration. On expiration the bronchus becomes narrowed, owing to its elastic tissue, which becomes effective with the cessation of the forces causing dilatation.

The forces causing physiologic dilatation acting on a bronchus which has lost much of its elastic and muscle tissue, such as occurs in bronchiectasis, will cause a greater dilatation than normal on inspiration, since there is not the elasticity to overcome. The bronchus will not return to its normal expiratory size with the cessation of the dilating forces, since its power of contraction is diminished on account of the loss of elastic and muscle tissue in its wall. Therefore the forces causing physiologic dilatation, if applied to a weakened bronchus, as found in bronchiectasis, will cause permanent or pathologic dilatation.

Added Factors Occurring in Bronchiectasis That Help to Cause Pathologic Bronchial Dilatation—Besides the forces of physiologic dilatation there are certain added factors in bronchiectasis that help to cause pathologic dilatation. These factors are atelectasis of the parenchyma, fibrosis of the parenchyma, and central bronchial obstruction. They increase the normal dilating force and may be of considerable significance in determining whether permanent dilatation (bronchiectasis) will occur or not.

1. *Atelectasis* Atelectasis of the parenchyma of the lung, which in my experience is of fairly common occurrence in bronchiectasis, increases the forces caus-

ing permanent bronchial dilatation in several ways. The pull of the expanding thorax on the bronchi will not be lessened by the intervening, inflated elastic parenchyma but will be transmitted directly to the bronchus through the solid atelectatic lung. There will result a greater pull on the bronchus. Also, with atelectasis, there will be a greater than normal pressure difference between that in the lumen of the bronchus and that outside its wall on inspiration. The increased intrapleural pressure found in atelectasis must be an index of increased pull on the bronchus and a greater pressure difference.

The normal telescoping movements of the bronchi and the passage of air through their lumens into and from the parenchyma on respiration are important factors in draining the bronchi of secretion. Atelectasis of the parenchyma, by interfering with the free passage of air along the bronchi and also with bronchial movement, causes a stagnation of secretion in the lumens. This secretion present in bronchiectasis has been given as one of the causes of the dilatation of the bronchi by its own weight or pressure, but this effect must be extremely slight. However, the infected material in the lumen of the bronchus must favor further infection of the wall of the bronchus, thus promoting increased weakening of the bronchial wall.

It is conceivable that a bronchus weakened by infection, such as occurs in bronchiectasis, might have the power to withstand some dilating force and not become permanently or pathologically dilated. However, if the bronchus is persistently subjected to the forces causing physiologic dilatation, and particularly if these forces are augmented by those which accrue as a result of atelectasis, permanent dilatation will result.

2. *Fibrosis of the Parenchyma* This is considered by many to be the chief cause of bronchiectasis. I believe that fibrosis and pleural adhesions when found in bronchiectasis are only supplementary factors increasing the physiologic dilating forces. They are rarely, if ever, the primary cause of the trouble in bronchiectasis. Fibrosis of the parenchyma will increase the dilating force in much the same way as atelectasis. There will be an increased direct pull on the bronchus as the force of the expanding thorax is transmitted directly through the solid lung. Also, as the parenchyma will be incapable of changing its air content on respiration, there will be very little flow of air along the bronchi, with subsequent stagnation of secretion and further damage to the all important bronchial wall.

3. *Central Bronchial Obstruction* This condition, in my experience, rarely occurs in bronchiectasis. However, a new growth or foreign body causing central obstruction is found in a definite percentage of cases. When this central bronchial obstruction is partial, it may produce a ball valve action. That is, on inspiration the lumen of the bronchus will widen at the site of the obstruction and allow air to pass distal to it. On expiration, the lumen of the bronchus will narrow and the central obstruction will either be increased or be made complete as the edge of the obstruction approaches the bronchial wall opposite to it. Thus, air will be partially or completely trapped in the bronchus distal to the obstruction. The slightly positive pressure present in the normal bronchi on expiration will be dissipated through the trachea into the atmosphere, whereas the positive pressure in the obstructed bronchus cannot be so readily equalized. Also, the return of the bronchus to its normal expiratory narrowed lumen, chiefly by elastic recoil, will be hindered by the entrapped air.

7 Robinson W. L. *Brit. J. Surg.* 21:302 (Oct.) 1933

8 Greey P. H. *The Bacteriology of Bronchiectasis* *J. Infect. Dis.*

1:203 (March) 1932

9 Macklin C. C. *The Dynamic Bronchial Tree*, *Am. Rev. Tuberc.*

25:393 (March) 1932

These factors will aid in the production of permanent or pathologic dilatation. Central bronchial obstruction has its greatest effect in causing bronchial dilatation during coughing, and especially if there is also peripheral bronchial obstruction or parenchymal fibrosis. Coughing without central bronchial obstruction increases the dilating force only because of the forced inspiration that precedes the closing of the glottis. The forces causing physiologic dilatation are greater with this forced inspiration than on quiet breathing. There appears to be no reason why that part of the coughing act during which the glottis is closed, or during which expiration is taking place, should cause dilatation unless there is central bronchial obstruction. The marked bronchial movements caused by coughing will also tend to cause permanent dilatation, because the bronchus with its decreased elasticity is further weakened by excessive movements. Also, as in atelectasis and fibrosis, the central bronchial obstruction interferes with proper drainage of secretion from the affected bronchus, with resulting damage to the bronchial wall.

CONGENITAL BRONCHIECTASIS

I have discussed the causes of permanent bronchial dilatation in acquired bronchiectasis. In practically all

Fig 1—Lobar atelectatic bronchiectasis. A plain roentgenogram showing triangular basal shadow in costodiaphragmatic area which is diagnostic of bronchiectasis. B after the injection of iodized oil into the bronchial tree showing the main bronchus to the right lower lobe communicating with dilated bronchi which are seen only in the area of the shadows.

cases of bronchiectasis, infection of the bronchial wall with destruction of its elastic and muscle coats is the primary fault and the bronchus subsequently becomes dilated, as a result of the factors considered. However, from time to time, reports appear of cases of congenital bronchiectasis supposedly the result of congenital or growth defects.

Congenital bronchiectasis should be diagnosed, either pathologically or clinically, with a great deal of hesitation. Henke and Lubarsch¹⁰ sum up the evidence by which congenital bronchiectasis may be diagnosed pathologically by stating that it is extremely difficult to be sure that bronchiectasis is congenital unless it is found in a fetus or new-born baby. Many of the cases diagnosed clinically as congenital I believe are acquired. Recently, I¹¹ described a series of cases of massive one-sided bronchiectasis showing many common characteristics. Cases similar to these have been described as congenital in origin, but they may be adequately

explained as acquired bronchiectasis, the permanent bronchial dilatation occurring because of factors already outlined. In this particular group of cases the added factor is, I believe, massive atelectasis of the parenchyma of one lung, and I have termed them "massive atelectatic bronchiectasis." The known etiologic factors causing acquired bronchiectasis may explain the origin of practically all cases of bronchiectasis. It seems unnecessary to postulate as a cause of bronchiectasis congenital defects, which usually cannot be proved either clinically or pathologically.

SYMPTOMS

The most common local symptoms of bronchiectasis are a chronic cough and sputum. There are certain characteristics about these symptoms that are almost diagnostic of bronchiectasis. Since this disease is a primary infection of the bronchus with marked destruction of its wall, one would expect that the cough reflex could not be elicited from it. The secretions in the diseased bronchi do not cause the cough reflex unless they leave these bronchi either by overflowing or by changes in posture, causing them to spill over into normal bronchi capable of causing a cough.

The character of the sputum is also significant. Formerly the classic picture of bronchiectatic sputum was about 1 pint of foul-smelling sputum, which separated into three layers on standing. This type of sputum is exceedingly rare. The average amount in our cases has been 4 ounces a day and only 20 per cent of our bronchiectatic patients have foul smelling sputum. However, there is one characteristic which is extremely suggestive of bronchiectasis and that is that the sputum is "chunky." This characteristic is explained by the fact that the diseased bronchus has lost to a great extent its normal movements which tend to flatten out excess secretion along the wall of the bronchus. The secretion tends to stagnate and the slight bronchial movements and small passage of air along the dilated bronchi allow the formation of this chunky sputum. Blood spitting is exceedingly common in bronchiectasis and occurred in 45 per cent of our cases. The infection in the bronchial wall after it has caused destruction may become so attenuated that no excess secretion is formed and "dry" bronchiectasis results. These cases without a cough or sputum are very uncommon and occurred in only 2 per cent of our series. The classic local symptoms of bronchiectasis, then, are a cough and sputum influenced by posture and the sputum moderate in amount, often accompanied by blood spitting and usually not foul smelling but practically always chunky.

The general or systemic symptoms are dependent chiefly on the condition of the parenchyma of the lung. A typical history of bronchiectasis is found in the patient in the twenties or thirties who consults a physician regarding a cough and chunky yellow sputum influenced by posture, which he has had since childhood following an attack of pneumonia or whooping cough. He has enjoyed excellent health and with the possible exception of one or two attacks of pneumonia is not bothered by anything but this constant cough and sputum. There is infection in the patient's bronchi but he has been fortunate in that the parenchyma of the lung has escaped to a large extent the infection permanently present in the walls and lumens of the bronchi. On the other hand, there is the patient who has chronic ill health due to spread of infection from bronchi to parenchyma, with resulting chronic low grade pneumonia. Acute pneumonia occurs frequently

¹⁰ Henke, Friedrich and Lubarsch, Otto, editors. *Handbuch der speziellen pathologischen Anatomie und Histologie*. Berlin: Julius Springer, 3, 1, 1928.

¹¹ Warner, W. P. *Quart J Med* 3: 401 (July) 1934.

in the bronchiectatic lung 52 per cent of our cases presented at least one attack and 27 per cent more than one attack after the onset of bronchiectasis. Bronchiectatic patients may also be greatly incapacitated because of repeated massive hemorrhages or be social outcasts due to fetid sputum.

SIGNS

Since the essential pathologic change in bronchiectasis is infection damaging the bronchial wall, one would expect the common physical signs to be dependent on this rather than on any parenchymal change. Dilated bronchi with excess, almost stagnant, secretion produce medium crackling râles which are by far the commonest physical sign in bronchiectasis. These râles are usually heard in the lower lobes, since bronchiectasis usually attacks these lobes; in only 2 per cent of our cases was it entirely located in the upper lobes. The parenchyma may be affected by chronic bronchopneumonia with resulting fibrosis, so that the physical signs of consolidation and fibrosis are present. Also the parenchyma may become atelectatic. Lobar atelectasis occurred in 16 per cent of our series and in about half of these the atelectatic bronchiectatic lobe could be diagnosed clinically as an area exhibiting impaired resonance, bronchial breath sounds and medium crackling râles, situated posteriorly along the spine and extending out in a triangular shape to the base of the lung. The common physical sign in bronchiectasis is the medium crackling râles persisting at one or both lower lobes.

ROENTGEN EXAMINATION

In bronchiectasis plain roentgen examination of the chest is usually negative or some thickening of the descending bronchial trunks may be observed. This is in keeping with the etiologic conception that bronchiectasis is a primary bronchial disease. So often is the roentgen report negative that its chief value lies in helping to rule out such conditions as tuberculosis as a cause of the patient's symptoms. When certain secondary changes, such as chronic bronchopneumonia and fibrosis, occur in the parenchyma, roentgen evidence becomes of value. If lobar atelectasis occurs in bronchiectasis, a triangular basal shadow (fig 1) is observed, which is diagnostic of this disease. These triangular basal shadows occurred in 16 per cent of our cases. They are the best diagnostic criteria found in plain roentgenograms of the chest in patients having bronchiectasis. These shadows were first described by Comby¹² and have been studied by Singer and Graham,¹³ Rist, Jacob and Trocme,¹⁴ Sargent and Bordet,¹⁵ Wallgren,¹⁶ and others. They have been considered due either to fibrosis of the bronchiectatic lung or to atelectasis of the parenchyma about the dilated bronchi. Graham and I⁹ found that these shadows have always represented a shrunken lobe containing bronchiectatic bronchi. We found that the bronchiectatic lobe was shrunken and took the shape that caused a triangular shadow on the x-ray film because of atelectasis of the parenchyma, not because of fibrosis. This atelectasis was due to inflammatory swelling of the walls of the peripheral bronchioles causing occlusion of their lumens with resulting deflation of the lung. The other plain x-ray picture that is diagnostic of bronchiectasis is seen in massive atelectatic bronchiectasis (fig 2). The thin whorl-like shadows present from apex to base, with mediastinum shifted to the affected side, are diagnostic of this unusual type of bronchiectasis.

Roentgen examination after injection into the bronchial tree of a radiopaque oil is the important diagnostic procedure to prove or disprove the presence of bronchiectasis. This simple procedure, almost devoid of danger, has been discussed elsewhere¹⁷ and will not be considered further here.

PROGNOSIS

It is obvious that the prognosis in bronchiectasis depends on the extension of the infection into the parenchyma of the lung or to other parts of the bronchial tree, or on the occurrence of massive pulmonary hemorrhage. So typical are the symptoms of bronchiectasis that I believe that the onset may in most cases be accurately determined from the history. By this means the duration of the disease, up to the time of writing in our series of bronchiectasis cases is estimated at ten years, the longest forty-two years. Patients may have bronchiectasis almost all their lives and die of some other disease. On the other hand, 23 per cent of our patients are dead after having the disease for an average of nine years; the shortest

Fig. 2.—Massive atelectatic bronchiectasis. A plain roentgenogram showing whorl-like shadows evenly distributed which are characteristic of this type of bronchiectasis. B saccular dilatations visualized after the injection of iodized oil.

duration in these fatal cases was three months. It is evident, therefore, that the prognosis varies tremendously with the individual case, from one with disease rapidly progressing to a fatal termination to one with practically no progression or disability.

TREATMENT

It is not within the scope of this paper to go into details regarding treatment. Some points arising as a result of this etiologic conception will be considered. It appears logical that if the physiologic dilating forces or any of the added factors causing bronchial dilatation could be held in abeyance during the time that the infection is acute and active in the bronchial wall, permanent dilatation might not occur. Artificial pneumothorax, for instance, by decreasing the dilating forces in acute bronchiectasis, might protect the bronchus until the infection subsides in its wall and it is able to withstand such dilating forces without becoming permanently dilated. In chronic bronchiectasis when permanent or pathologic dilatation has occurred, little can be expected from collapse therapy. When central bronchial obstruction can be removed this should be done,

thus eliminating a factor causing increased dilating force and impaired bronchial drainage

When bronchiectasis has become established, with secondary changes in the parenchyma, medical treatment consists of draining the dilated bronchi. This can be accomplished most satisfactorily by adequate postural drainage. Bronchoscopic drainage is of use chiefly as a means of improving postural drainage by removing some central bronchial obstruction, such as a foreign body, growth or granulation tissue.

Surgical treatment has made tremendous advances in recent years. When permanent or pathologic dilatation has taken place, surgical removal of the diseased lung is the only method of "cure," as the bronchi never return to their normal size by other forms of treatment. However, with such a high operative mortality still present in lobectomy, the patient must have considerable disability before operation is advised.

CONCLUSIONS

1 The primary fault in bronchiectasis is a non-specific infection of the bronchial wall causing destruction, particularly of the muscle and elastic tissues present.

2 The weakened bronchus then becomes permanently dilated, owing to the forces causing physiologic bronchial dilatation.

3 There are certain added factors: atelectasis of the parenchyma, fibrosis of the parenchyma, and central bronchial obstruction, which increase this physiologic dilating force and tend to produce permanent or pathologic dilatation.

4 The conception of bronchiectasis as a primary disease of the bronchus secondarily affecting the parenchyma alters the interpretation of signs and symptoms and the application of therapy.

100 College Street

ABSTRACT OF DISCUSSION

DR. DAVID T. SMITH, Durham, N. C. I have been studying bronchiectasis for the last ten years and agree with Dr. Warner's statement that the primary fault in bronchiectasis is an infection of the bronchial wall with destruction of the elastic and muscular coats. I am particularly interested in the types of infection that can destroy the elastic tissue and muscle in the bronchial wall. The tubercle bacillus can and occasionally does destroy the bronchial wall and produces the iodized oil picture of bronchiectasis. Staphylococci necrotize pulmonary tissue and can probably destroy elastic tissue and muscle in the bronchi. The fusospirochetal group of organisms that ulcerate the tonsils, necrotize the lung and destroy bone can undoubtedly destroy the elastic and muscular coats of the bronchi. Chevalier Jackson has seen this occurring in the bronchi of man through the bronchoscope and I have produced the iodized oil and pathologic picture of bronchiectasis in rabbits with the fusospirochetal organisms. In 1930 I reported a series of sixty cases of bronchiectasis in which the lesion was demonstrated by the injection of iodized oil. Forty-nine of the sixty cases showed fusiform bacilli and spirochetes in the sputum. These cases were under observation for many months and had repeated sputum studies. In a general hospital, where the patients cannot have repeated examinations for such long periods, one would not expect to find as high a percentage of fusospirochetal organisms. As a check on my own enthusiasm for these organisms I collected the results of the sputum studies on the cases of bronchiectasis seen in the Duke Hospital during the last four years, the examinations being made by the regular house staff and routine laboratory. The bronchiectasis was diagnosed in thirty cases by injections of iodized oil and in two at necropsy. Spirochetes and fusiform bacilli were found in the sputum in eighteen cases. Staphylococcus aureus was found in eight cases and various types of other organisms in six cases.

When fusiform bacilli and spirochetes are present in the sputum, I believe that the postural drainage treatment should be supplemented by injections of neoarsphenamine. If there is no evidence of improvement with this treatment within a month, bronchoscopy should be tried and, if this also fails, surgery is indicated.

DR. HAROLD BRUNN, San Francisco. A study of cases of bronchiectasis at the University of California Hospital Thoracic Clinic substantiates in the main the thesis promulgated by Dr. Warner in his paper. There can be no doubt in reading the history of the cases that we have had, especially severe ones, that infection early in life is the distinguishing feature. However, I still feel that infection is not the only factor involved. There are certain cases of congenital bronchiectasis which I believe are present and brought to the attention of the physician only when infection supervenes. The only method by which this point can be evaluated is by a more careful roentgen study of children in early life, especially those whose deliveries have been difficult and in whom atelectasis occurs. However, at the present time roentgenograms of small children are very difficult to interpret and iodized oil studies are practically impossible. The rabbit as an animal for experimentation is a poor choice, as it is frequently subject to bronchiectasis. I am fully in accord with Dr. Warner as to the physiology involved in the formation of the sacculations in regard both to the atelectatic lung and to the dilating force of inspiration. Experimental work along these lines was carried out in our laboratory by Drs. Prinzmetal and Brill. Dr. Prinzmetal has since then continued this work at the Barnes Hospital, Washington University, a report of which appeared last year in the *Journal of Allergy*.

CLINICAL STUDY UNDER CONTROLLED CONDITIONS OF 1,083 CHILDREN WITH HOOKWORM

A. E. KELLER, M.D.

J. T. GOOGE, M.D., C.P.H.

H. B. COTTRELL, M.D., C.P.H.

D. G. MILLER, JR., M.D.

AND

R. H. HARVEY, M.D.

NASHVILLE, TENN.

A recent investigation¹ of the hookworm problem in Mississippi revealed that there had occurred a marked decrease in both incidence and intensity of hookworm infestation since 1914. No recent clinical studies of hookworm have been made to determine its effects on the health of school children under these conditions of lowered prevalence and intensity of infestation. Since methods are now available by which with a fair degree of accuracy the physical condition of the patient can be studied in relation to the hookworm burden, the present report deals with such a study among rural school children in George County, located in south eastern Mississippi.

This particular area was studied because it was known that 40.8 per cent of 1,618 white persons were found in that county to have hookworm during the recent state-wide study in Mississippi. Since it has been established that the highest incidence and intensity of infestation of hookworm is found in the school age group, from 5 to 18 years inclusive, and as the most severe symptoms of hookworm disease are found in

Drs. Miller and Harvey were students in the fourth-year medical class at the time this work was done.

From the Department of Preventive Medicine and Public Health of Vanderbilt University School of Medicine, in cooperation with the State Department of Health of Mississippi, and aided by a grant from the International Health Division and Division of Medical Sciences of the Rockefeller Foundation.

this group of the population, the present study concerning the clinical manifestations was confined to individuals of this age period

The plan of study was projected so that there would be for each child studied a medical and dietary history and a complete physical and blood examination. The hemoglobin determinations were made by the Sahl

TABLE 1—Intensity of Hookworm Infestation*

* One thousand and eighty three specimens of feces examined by both the salt flotation and Stoll dilution egg-counting technique

method with hemoglobinometers standardized against a solution the hemoglobin content of which had been determined gasometrically. An examination of the blood by the thick drop method for malaria parasites was also included, to rule out a condition that might complicate or produce symptoms and signs similar to those of hookworm disease. Individuals in whom plasmodia were found in the blood and also those showing parasitic infestations other than hookworm were excluded from this series of cases. A specimen of feces was obtained from each individual and each specimen was examined by both the salt flotation and Stoll dilution egg-counting techniques. A total of 1,083 school children were studied according to the plan outlined. This represents approximately 59 per cent of the children of school age in the county.

In order to obtain a control series, all children whose specimen of feces contained no hookworm eggs as determined by examination with both the salt flotation and egg-count methods were placed in one group. These children all lived in the same families and under similar environmental and dietary conditions as those who were found to have hookworm. Of the 1,083 specimens of feces examined 222, or 20.5 per cent, were negative by both the salt flotation method and the egg count. This group is considered as a control series.

Of the 1,083 specimens there were 861, or 79.5 per cent, positive on salt flotation and 635, or 58.6 per cent, positive on egg count. This difference of 19.9 per cent more specimens found positive by the salt flotation method than by egg count is accounted for by the greater efficiency of the salt flotation technic in detecting hookworm eggs in specimens of feces containing only a small number of ova. Practically all individuals who are found to have hookworm under these conditions have very light infestations.

The intensity of infestation of the specimens found positive on egg count is shown in table 1.

If an intensity of infestation of 2,600 or more eggs per cubic centimeter of feces, or 100 or more hookworms, is taken as the level at which clinical symptoms may be expected to be present table 1 shows that only 187, or 17.3 per cent, of the specimens examined showed infestations which were probably the cause of

symptoms. If the group of specimens designated "salt flotation positive, egg count negative" are considered as very light infestations, it is seen that 62.2 per cent of all the specimens showed very light or light infestations and 20.5 per cent were negative. In the tables that are to follow, the approximate number of hookworms will be shown rather than the number of eggs per cubic centimeter of feces. The group of cases that were positive on salt flotation but negative on egg count are also included with the very light group.

HISTORIES

The symptoms of hookworm as shown by the history records of 1,083 children have been analyzed according to the intensity of infestation. There were no significant differences found in the different intensity groups for such symptoms as anorexia, digestive disturbances, abdominal pain and discomfort, disturbed sleep and restlessness. Approximately as many children complained of these symptoms in the control group as in the groups showing variations in intensity of infestation. There was, however, a definite correlation between the intensity of infestation and such symptoms as fatigue, weakness, dyspnea and edema. This analysis is shown in table 2.

In analyzing table 2 it is found that in the negative or control series the percentage of persons complaining of fatigue, weakness, dyspnea and ground itch was lower than in any of the hookworm infested groups. There is rather marked variation in the light intensity groups and it is only when an infestation of 100 worms or more is reached that there is decided increase in the percentage of individuals complaining of these symptoms. Not only were there larger numbers of children with moderate and heavy infestations complaining of fatigue, weakness and dyspnea but it should be stated that the degree of fatigue, weakness, dyspnea and edema was more marked in these children with moderate and heavy infestations than in those of the lower intensity groups.

A history of ground itch has always been considered a cardinal symptom of hookworm disease and in this series of cases children giving a history of ground itch

TABLE 2—The Correlation of Symptoms with Intensity of Hookworm Infestation

| Approximate Number of Hookworms | Number Examined | Fatigue | | Weakness | | Dyspnea | | Edema | | Ground Itch | |
|---------------------------------------|--------------------|---------|----------|----------|----------|---------|----------|--------|----------|-------------|----------|
| | | Number | Per Cent | Number | Per Cent | Number | Per Cent | Number | Per Cent | Number | Per Cent |
| Negative | 222 | 31 | 14.0 | 31 | 14.0 | 33 | 12.6 | 12 | 5.4 | 76 | 34.2 |
| 0 to 24 | 415 | 96 | 23.1 | 94 | 22.7 | 56 | 13.5 | 16 | 3.9 | 242 | 58.3 |
| 25 to 50 | 169 | 61 | 36.3 | 44 | 26.0 | 39 | 23.0 | 13 | 7.7 | 100 | 61.1 |
| 51 to 100 | 90 | 19 | 21.1 | 23 | 24.4 | 19 | 21.1 | 3 | 3.3 | 60 | 75.0 |
| 101 to 500 | 161 | 50 | 31.0 | 49 | 30.4 | 43 | 26.7 | 10 | 10.0 | 132 | 82.0 |
| 501 to 1,000 | 13 | 8 | 61.5 | 8 | 61.5 | 7 | 53.8 | 4 | 30.7 | 11 | 84.6 |
| 1,001 and over | 13 | 9 | 69.2 | 8 | 61.5 | 7 | 53.8 | 2 | 15.3 | 8 | 61.5 |

were studied with reference to the significance of this symptom. The data show that 34.5 per cent of the negative or control group and well over half of those with hookworm gave a history of ground itch. Moreover, conditions conforming to the clinical manifestations of ground itch were found not infrequently in children during the examination.

PHYSICAL EXAMINATION

The results of the physical examinations are shown in table 3. In order to evaluate the effect which foci of infection may produce and obscure the conditions

produced by hookworm infestation, an analysis of those individuals in whom diseased teeth and tonsils were found on physical examination is included. Only those tonsils which the observer was reasonably sure were diseased are included in this analysis.

One of the most striking observations on physical examination was the large percentage of children in each group who were underweight. Only those children who were either 10 per cent above or 10 per cent below the weight for their heights were considered overweight or underweight as determined by the standards of the American Child Health Association. Table 3 shows that from 56.6 to 71.5 per cent of the children examined were underweight, from 24.5 to 37.8 per cent were normal weight, and from 0.7 to 5.7 per cent were overweight. It was found that for all intensity groups the average underweight was 17.7 per cent and there was a variation between the different groups of from 16.3 to 20.0 per cent. However, there was only a slight variation in the degree of underweight in the various intensity groups as compared with the control series.

The figures for weights show that in the moderate and heavy infestations there is some increase in the percentage of children who were underweight. Table 3 shows also that the percentage of children underweight

number in the control group with this condition was about the same as in the groups showing hookworms. The data show that diseased teeth and tonsils were equally distributed throughout all groups examined and these conditions should be considered as probable factors influential in causing the malnutrition and anemia found.

BLOOD EXAMINATION

In making the blood counts the red and white cell pipets containing the diluted blood were placed in a mechanical device (rotor) in order to obtain more uniform dispersion of the cells in the diluting fluid. This method has been described by Bryan and Garrey. The precautions regarding fresh diluting fluid for the red blood cell counts were observed as suggested in their paper. The method used for hemoglobin determination has already been described. In making the differential leukocyte counts, slide smears were stained with Wright's blood stain. Two hundred leukocytes in each specimen were counted.

The results of the examination of the blood are given in table 4, which has been arranged to show the average results in both the control group and the different intensity levels of those infested with hookworm.

A discussion of the data concerning the blood examination is based on the normal values of the constitu-

TABLE 3—Correlation of Results of Physical Examination with Intensity of Hookworm Infestation

| 101 to 500 | 101 | 45 | 21.8 | 1 | 0.7 | 115 | 71.5 | 16.3 | 51 | 31.7 | 86 | 33.4 | 76 | 47.2 | 30 | 18.6 |
| 501 to 1,000 | 13 | 5 | 38.3 | 0 | 0.0 | 8 | 63.7 | 18.0 | 6 | 46.0 | 9 | 70.0 | 6 | 46.0 | 4 | 30.7 |
| 1,001 and over | 13 | 3 | 23.1 | 0 | 0.0 | 9 | 71.5 | 20.0 | 7 | 53.8 | 11 | 84.6 | 8 | 61.5 | 5 | 40.0 |

is essentially the same in the negative group as in the groups showing light and moderate hookworm infestations. Obviously there were factors operating other than hookworm to bring about this condition in both the infested and the noninfested groups. Although it is not possible to compare the data concerning the heights of the children examined in this series with the heights of a comparable group of normal children, the impression was gained that for the study as a whole a majority were undersized generally.

The clinical observations of the skin and mucous membranes showed in general that the percentage of individuals with anemia increased with the intensity of hookworm infestation. Of the individuals who were in the negative or control group, 41.4 per cent were recorded as having clinically some degree of pallor of the skin and mucous membranes.

Physical examinations revealed that the percentage of children with poor nutritional status is slightly higher in the group with light hookworm infestation than in the control group, and it is definitely higher in the groups with moderate and heavy infestations.

The percentage of children with diseased teeth in the different groups showed no significant variation. From 42.9 to 61.5 per cent of the children in each group in this series had diseased teeth. Practically the same figures were obtained in regard to diseased tonsils. From 18 to 40 per cent of all the children in each group were recorded as having diseased tonsils. The percentage of children with diseased tonsils in the different intensity groups did not vary much and the

ents of the blood of children in corresponding age groups as are under consideration in this study. The average red blood cell count and hemoglobin estimation² for normal children 5 years of age is stated to be 4,500,000 red blood cells per cubic millimeter and 85 per cent hemoglobin, 100 per cent being used as equivalent to 16 Gm. For normal children 10 years of age the average is 5,000,000 red blood cells and 90 per cent hemoglobin. For both age periods 8,000 white blood cells per cubic millimeter is the normal average. If these figures for the hemoglobin should be translated into grams per hundred cubic centimeters to correspond with the method of determination used in this series of observations, the average normal of 5 years would be 13.6 Gm and for 10 years would be 14.4 Gm per hundred cubic centimeters of blood.

There was a secondary anemia in all groups with hookworms as well as in the control series. However, there was very little difference in the negative group as compared with those having light infestations. There was no appreciable decrease in the red blood cell counts and hemoglobin until an infestation of 100 hookworms or more is reached, in which groups there was a greater decrease in hemoglobin. Those children having the heaviest worm burdens were on the average more anemic than those having either no hookworm or light infestations.

² Bryan W. R., and Garrey W. E. A Mechanical Device That Produces Uniform Dispersion of Blood Cells in the Diluting Pipet. *J. A. M. A.* 103: 1059-1060 (Oct. 6) 1934.
³ Holt L. E., and Howland John. *Holt's Diseases of Infancy and Childhood*, ed. 10. Revised by L. E. Holt Jr. and Rustin McIntosh. New York: D. Appleton & Co. 1935. p. 529.

In individual cases, anemias as severe as those found in the children with moderate and heavy hookworm infestations were also found in children having light infestations. In the control group, 18 per cent had anemias as severe as those found with moderate and heavy infestations. Therefore it is apparent that hookworm infestation alone does not account for the anemia, as the same degree of secondary anemia was found in a significant number in each of the groups

TABLE 4—Results of Blood Examination *

| Approximate Number of Hookworms | Number Examined | Red Blood Cells Millions per Cu Mm | Hemoglobin Grams per 100 Cc | White Blood Cells Thousands per Cu Mm | Per Cent Eosinophils | Per Cent with Normal Number of Eosinophils |

* Average red and white blood cell counts, hemoglobin determination and eosinophil count according to intensity of hookworm infestation

The average leukocyte count was found to be within the limits given by Holt and Howland³ (1933). There was no relationship between the intensity of infestation and the leukocyte count. In each group there were a few counts above 10,000 cells per cubic millimeter, one of these being 18,700. There were only seventeen counts below 5,000, the lowest being 2,750.

The differential leukocyte counts revealed normal distribution of the cells except for the eosinophils. Table 4 shows that in the control group an average of 9.6 per cent of the white cells counted were eosinophils. Only 3.6 per cent of the counts in the negative group contained less than 5 per cent, which is considered the upper limit of normal. This abnormally high eosinophil count in a large number of individuals without intestinal parasites may be explained in part by the fact that this investigation was carried on during the season most favorable for the transmission of hookworm. Under these conditions it would be possible to find an increase in the eosinophil resulting from migration of hookworm larvae even though examination of the feces revealed no hookworm eggs. Similar instances have been reported in which this occurred during the period of migration following massive infection with hookworm larvae.⁴

In the infested groups no relationship between the worm burden and the percentage of eosinophils could be determined. In each group there was an increase in the eosinophils, the average varying from 11.9 to 17.9 per cent. In from 4.3 to 17 per cent of the blood specimens obtained from children known to have hookworm, the number of eosinophils was within normal limits. The smallest number of normal eosinophil counts was found in the group showing from 100 to 500 worms. These data indicate that while in a majority of individuals with hookworm there is usually found an increase in the eosinophils, there also may be no increase in these cells.

DIETS

The data relative to the diets of the individuals studied in this series were obtained by questioning the parents and recording on special forms the information

relative to the amounts of the usual types of food ordinarily consumed, such as milk, cereals, meat and eggs, fruits and vegetables. Information concerning the use of accessory foods, such as cod liver oil, orange and tomato juice, and yeast also was obtained. Notation was made as to whether none or very small amounts of these substances were eaten or whether moderate to large amounts were included in the usual diet. Data relative to dietary habits are difficult to obtain, but we believe that the dietary data obtained in this study is representative of the area under consideration.

Table 5 contains these data which have been prepared so as to show the relative amounts of these substances usually consumed. The figure 1 under each heading indicates that either none or very small amounts of the particular food were eaten and the figure 2 represents either moderate or large amounts. Figure 1 represents inadequate amounts and figure 2 adequate amounts of the various foods. The figures in the columns represent the percentage of persons in each group. In order to conform to the procedure used in reporting the other observations the dietary data will be given according to the various intensities of infestation.

Table 5 shows that on the whole the amounts of the different foods consumed by all groups were inadequate except vegetables. Inquiry as to the kind of vegetables eaten indicated that most of the vegetables consisted of dried beans and peas. Only small amounts of green leafy vegetables were eaten. It was also found that the term meat was used to indicate salted fat pork with a very small amount of lean pork in it. This was the usual type of meat used, though small amounts of eggs, beef, chicken and fish were eaten. The constituents of the diet also were on the whole lacking in animal protein and hematopoietic substances. It can be said that the diets were not only inadequate in amount but also very poorly balanced.

One of the striking features concerning the diet was the extremely small number of children who had

received additional food substances in the form of vitamins. From 98 to 100 per cent of all children had received none of these foods. It would seem reasonable to state that the lack of adequate amounts of food together with the poor balance of the diet and lack of additional vitamins was responsible in a great measure for the large percentage of children shown to be underweight and undersize. It is therefore reasonable to assume that the unsatisfactory dietary conditions may be considered an important accessory factor in causing the secondary anemia associated with hookworm infestation.

⁴ Ashford B. K. Payne, G. C. and Payne Florence K. Acute Uncinariasis from Massive Infestation and Its Complications. J. A. M. A. 101: 843-847 (Sept. 9) 1933

Table 5 shows that with the increase in the intensity of infestation the diet became more inadequate in substance except vegetables (dried beans and peas). This was probably due to the economic condition in certain parts of the county under study, because the records show that those communities in which the highest incidence and the greatest number of heavy infestations were found were the poorest and had the largest number of families on the direct federal relief rolls. It should be stated, however, that the diet in those communities in which the economic conditions were better, while somewhat improved, were not satisfactory. It would appear that dietary insufficiencies were possibly almost or fully as important in bringing about the abnormal blood conditions noted as any other factors. Although hookworm infestation is conducive to increasing the anemia, it should be noted that the same dietary faults and the same degree of malnutrition were found in the groups without hookworm as in the groups with hookworm.

COMMENT

This study shows that there is a correlation between the physical condition of children infested with hookworm and the worm burden. This relationship is not striking, however, until the intensity of infestation reaches a level of moderate to heavy infestation (100 or more hookworms). In these intensity groups as compared with the negative or control group and those with light infestations there were more children complaining of symptoms such as fatigue, weakness, dyspnea and edema. The degree of these symptoms was also more marked in these children. They were also more anemic as compared with those who either had no hookworm or had light infestations.

Certain conditions were found to essentially the same extent in all groups, including the control series. The observations relative to secondary anemia, poor dietary conditions, malnutrition, underweight, diseased teeth and tonsils were especially striking. In the presence of these conditions the clinical manifestations produced by hookworm infestation are likely to be more marked than if complicating factors were not present. It seems likely, especially in the light and very light cases, that factors other than hookworm were in part at least responsible for bringing about the physical condition of the children examined.

It has been shown by workers in Puerto Rico⁵ that where satisfactory diets containing iron can be provided the effects of hookworm infestation can be decreased without removing the hookworms. In considering the measures that are necessary to improve the physical conditions of children living under such conditions it is necessary to reduce the environmental hazards, such as improper excreta disposal, and to eradicate the hookworms present. The removal of foci of infection, with provision of satisfactory diets and the use of iron following treatment, especially in the heavy infestations, are necessary procedures if the normal health level of children in these areas is to be maintained.

SUMMARY

1 In a series of 1,083 children it was found as a result of the examination of a specimen of feces for hookworm eggs that 222, or 20.5 per cent, were negative and that 79.5 per cent were infested. Of those

infested 674, or 62.2 per cent, had very light or light infestations and 187, or 17.3 per cent, had moderate and heavy worm burdens.

2 As regards the symptoms of which these children complained, no significant differences were noted in either group for such disturbances as dyspnea, weakness and fatigue, and edema until an infestation level of approximately 100 or more hookworms was reached. Not only did a larger percentage of children complain of these symptoms when the intensity of infestation reached this level but also the degree of dyspnea, weakness and fatigue, and edema was increased.

3 For all groups studied, from 56.6 to 71.5 per cent were underweight as determined by accepted standards. There was only slight variation in the degree of underweight in the infested groups as compared with the controls.

4 The data relative to anemia and malnutrition as determined by physical examination indicate no striking differences between the negative or control group and the very light and light infestations. Those individuals showing the heaviest worm burdens had the greatest degree of anemia and malnutrition. Anemia was noted, however, in 41.4 per cent of the 222 children in the control series.

5 Diseased tonsils and teeth were present to almost the same extent in both the control group and in each group with hookworm.

6 The red blood cell counts and hemoglobin determinations show a secondary anemia in all groups, the degree of anemia being greatest in those children with infestations of 100 or more hookworms. It was found that 18 per cent of the control series and from 22 to 27 per cent of those with very light and light infestations had the same degree of anemia as those with moderate and heavy worm burdens.

7 No significant deviations from the normal leukocyte counts were found.

8 An increase in number of eosinophils was found in all groups, the control group averaging 9.6 per cent. The average eosinophil count for those known to have hookworm varied from 11.9 to 17.9 per cent.

9 In the groups with hookworm, from 4.3 to 17 per cent had eosinophil counts less than 5 per cent. No relationship between the percentage of eosinophils and the number of hookworms could be determined.

10 Data relative to the dietary habits of the children studied showed that on the whole the diets were not only inadequate in amount but also poorly balanced and lacking in hematopoietic substances. The main components of the diet consisted of cereals, dried beans, peas and meat, which was salted fat pork. Only small amounts of animal protein, milk and eggs were consumed. Only a small number of children in the entire group received additional accessory food substances such as cod liver oil, orange or tomato juice.

CONCLUSIONS

The conclusions drawn from this study are based on conditions as they exist at the present time in George County, Mississippi. It is apparent that there is a high incidence of hookworm in the county studied, but a majority of infested children have very light or light worm burdens. It would seem that the other conditions such as anemia, malnutrition, probable foci of infection and poor diets should be given attention in any evaluation of the effects of hookworm infestation in the population studied, as these conditions were frequent in both control and infested groups.

⁵ Rhoads, C. P., Castle, W. B., Payne, G. C. and Lawson, H. A. Observations on the Etiology and Treatment of Anemia Associated with Hookworm Infestation in Puerto Rico. *Medicine* 13: 317-375 (Sept.) 1934.

In the early days of hookworm control in this country it was necessary to institute extensive treatment campaigns on account of the severity of the disease. It is reasonable to state that hookworm control now should be considered as part of a well balanced public health program. The removal of the hookworm alone will bring about only partial and temporary improvement in the health of children. Attention should not be focused on hookworm infestation alone to the exclusion of other conditions that may be as important as hookworm in producing ill health.

THE USE OF UNSATURATED FATTY ACIDS IN THE TREATMENT OF ECZEMA

(ATOPIC DERMATITIS, NEURODERMATITIS)

SAMUEL J. TAUB, M.D.

AND

SAMUEL J. ZAKON, M.D.
CHICAGO

About two years ago, Hansen¹ conceived the idea of investigating the possible clinical bearing of a discovery made in 1929 by Burr regarding the requirement for unsaturated fatty acids in animal nutrition. Burr found that rats placed on completely fat free diets, but adequate in all other respects, soon developed a definite syndrome characterized in the early stages by scaliness of the skin and in the later stages by cessation of growth, necrosis of the tail and pathologic alterations in the kidneys. When, however, he added fats to the diet of these experimental animals, they again began to grow and the skin scaliness disappeared entirely.

Hansen found that the iodine absorption value of the blood serum of eczematous babies is low and that it increases with clinical improvement. He could produce an increase in the serum iodine by feeding these babies linseed oil and he also reported a number of clinical cures by feeding linseed oil.

Cornbleet,² working independently, reported on the treatment of eczema (atopic eczema, neurodermatitis), in adults with maize oil. The essential substances of these unsaturated fatty acids are apparently linoleic, linolic and possibly arachidonic acids.

Utilizing the preliminary observations of these workers, a number of pharmaceutical houses are exploiting these unsaturated fatty acids to the medical profession with claims that are entirely unwarranted. These unsaturated fatty acids are now sold at an exorbitant price, with exaggerated claims for the treatment and cure of such conditions as eczema, alopecia, asthma and other allergic conditions.

In our clinical experience with linseed oil, covering a period of eight months, we have used a purified linseed oil as advised by Hansen, in doses of from one-half ounce to 1 ounce (15 to 30 cc) three times a day. Our series comprises only eight patients with eczema (atopic dermatitis, neurodermatitis). These patients are the only ones of a larger number who carried out this treatment faithfully. Our results with these eight patients were universally poor. Two of these patients, while taking the linseed oil, developed crops of oily cysts and furunculosis. Another patient

had a severe asthmatic attack after taking the linseed oil. The asthma developed the first day the oil was taken and skin tests with powdered linseed and cottonseed were strongly positive. No allergic tests were made on any of these patients and we did not include the patient who developed asthma in this series. One of the distributors of a linseed oil specifically states in its advertisement to doctors that asthma is benefited while under this treatment. In a previous article, one of us³ cited the relatively large incidence of cottonseed as a cause of asthma, hyperesthetic rhinitis and associated allergic disturbances. Botanically related seeds such as linseed, kapok seed, peas and beans may also produce an allergic disturbance in a patient sensitive to cottonseed. Therefore the danger of promiscuously prescribing a linseed oil product for an eczema patient is apparent.

In none of these patients could we see any improvement in the clinical appearance of the eczema. In view of these results we have discontinued the use of the unsaturated fatty acids in the treatment of atopic eczema and we conclude that the promiscuous use of linseed oil as advocated by the distributors of this product is entirely unjustified and not without danger if used for a patient who may be cottonseed or linseed sensitive.

185 North Wabash Avenue.

HERNIA REDUCED EN MASSE

LOUIS H. NASON, M.D.

AND

CHARLES G. MIXTER, M.D.
BOSTON

An unusual and dangerous complication of hernias is reduction *en masse*. This condition nearly always creates an emergency, since false reduction almost inevitably causes strangulation of the hernial contents. The gravity of such a situation makes it necessary to consider the possibility of hernia reduced *en masse* whenever certain characteristic clinical features are present.

This condition was recognized as early as 1702, when Saviard¹ first noted its occurrence. Conner and Howitt² in 1908 collected five instances in 1,618 cases of strangulated hernia at the St. Thomas and St. Bartholomew hospitals. Pearse³ in 1931 published a statistical study based on 193 cases collected from the literature. Force and taxis appear to be the precipitating factors in 93 per cent of the cases. It occurs more commonly in males than in females, usually on the right side, and in inguinal rather than in femoral hernias. Pearse found only 12 per cent of the cases in femoral hernias.

The following case reports serve to illustrate the typical history and physical observations in patients with hernia reduced *en masse*. Three of the five cases occurred in a group of 632 hernias of all types, of which seventy-three were strangulated or incarcerated. It is noteworthy that in none of these cases was undue force or taxis a prominent feature in the history.

REPORT OF CASES

CASE 1.—D. F., a man aged 50, entered the hospital complaining of generalized abdominal cramps beginning suddenly

six hours before entrance. The pain gradually shifted to the right lower quadrant of the abdomen and was followed by nausea and vomiting. At the onset he noticed a tender bulge in the right inguinal region, but this soon disappeared spontaneously. Seven years previously he had had a bilateral inguinal herniorrhaphy and appendectomy.

Examination revealed a distended abdomen with waves of peristalsis traveling from left to right. There was no evidence of a recurrence of either inguinal hernia. However, over the right saphenous opening there was a distinct defect, which allowed the admission of the examining finger to a depth of about $1\frac{1}{2}$ inches. Only a feeble impulse could be felt on coughing, but no distinct mass was palpable.

Under spinal anesthesia a right lower rectus incision was made. Dilated bowel presented. This bowel led to a right femoral hernia, the sac and unreduced contents of which protruded into the abdominal cavity. The neck of the sac was incised, and an incarcerated loop of ileum dark and discolored was liberated. The circulation of the loop returned satisfactorily. The sac was inverted into the abdominal cavity and removed after ligation of the neck. The convalescence was uneventful and the patient was discharged on the fourteenth postoperative day.

CASE 2—B S, a man aged 48 entered the hospital complaining of abdominal pain and vomiting of two days' duration. He had had bilateral inguinal hernias for the past fifteen years, which had always been reducible. Six days before admission he developed cramplike pain in the left lower quadrant of the abdomen and in the region of the hernia, which had become incarcerated. He reduced the hernia and the symptoms subsided but recurred two days before admission. He began to vomit with increasing frequency and severity. He became obstipated, and enemas produced neither feces nor flatus. The right hernia was always reducible. The left hernia had not reappeared since the previous "reduction" six days previously.

The patient was dehydrated, and the abdomen was markedly distended and tympanic. On the right side there was a reducible, nontender inguinal hernia but on the left side the examining finger could be inserted through the external inguinal ring into a definite defect. No hernial mass could be palpated. The temperature by rectum was 100.4°F , the pulse rate 130.

Under spinal anesthesia, a left lower paramedian incision was made. The small bowel was found markedly dilated. This was traced down to the left internal inguinal ring where a distinct bulge into the peritoneal cavity was noted. This consisted of a hernial sac with incarcerated and strangulated small bowel, the whole entirely out of the inguinal canal and occupying a retroperitoneal position. The neck of the sac was incised and the bowel liberated. It was deeply discolored but appeared viable. The sac was dealt with by inverting it and amputating it after transfixion at the neck. The immediate convalescence was stormy, the patient developing evidences of paralytic ileus. This was successfully treated, and the convalescence proceeded uneventfully.

CASE 3—J F, a man aged 65, entered with a history of having had bilateral inguinal hernias for ten years. Three days before admission the left hernia protruded to the size of a large plum. He experienced some difficulty with it and therefore resorted to a warm bath, in which it apparently became reduced. Two hours later he began to experience generalized abdominal cramps, with nausea, and three hours after the "reduction" he vomited. The vomiting and the cramps continued to the time of entry.

The abdomen was markedly distended, and waves of peristalsis could be seen traveling over the upper half. The right inguinal region contained an easily reducible hernia. In the left inguinal region the external ring was dilated and easily admitted the examining finger. There appeared to be a definite defect in the floor of the canal, with only a weak impulse on coughing. The temperature was 100°F rectally, and the pulse rate 120.

Under general anesthesia a left rectus incision was made. The small bowel was definitely distended, the distended portion being traced down to the left internal inguinal ring. This ring appeared displaced directly into the abdominal cavity by

a large sac containing small bowel. The bowel could not be liberated by gentle traction. Therefore the ring was incised at its upper aspect, and about 9 inches of dusky, cyanotic ileum delivered. Its surface was almost completely covered by ecchymotic hemorrhages. There were definite constriction rings present at both efferent and afferent loops. After ten minutes the circulation appeared to have returned satisfactorily. A Witzel type of enterostomy was performed, the catheter emerging through a stab wound.

Shortly after operation the patient manifested a moderate degree of shock. This was successfully combated with intravenous infusion of saline and dextrose solutions. However the blood pressure again dropped and the temperature rose to a terminal height of 105.8°F . The patient lapsed into coma and died twenty-four hours after operation.

His death appeared to be due to gangrene of a supposedly viable loop of ileum, or to a gas bacillus infection.

CASE 4—E W, a man, aged 59, was referred to Dr C G Mixter complaining of vomiting of five days' duration. Since the onset of the vomiting his abdomen became distended and he had no bowel movement. For the past seven years he had been aware of a moderate sized right inguinal hernia. Three days before the onset of the vomiting, the hernia became incarcerated. However, it was reduced without undue difficulty and there had been no pain in this region since.

The abdomen was markedly distended and tympanic throughout. The right external inguinal ring was dilated, and a definite defect could be felt in the floor of the canal. When the patient coughed a slight impulse was felt, and a vague mass appeared to descend and strike the tip of the examining finger. The pulse rate was 90. The temperature was 98.4°F rectally.

Several enemas were given with no results. Therefore, under ether anesthesia the abdomen was opened through a 6 inch right paramedian incision. The loops of small intestine were greatly distended and injected. Exploration of the right internal inguinal ring revealed a tumor mass the size of an orange. The tumor was composed of a hernial sac with a neck three-fourths inch in diameter and containing bowel, the whole having been reduced *en bloc*. The neck of the sac was incised, permitting reduction of the strangulated loop. The bowel was cyanotic and showed two pressure rings. It was viable, however. The usual herniorrhaphy incision was then made, and a routine herniorrhaphy was then carried out.

The convalescence was rather stormy and marked by persistent distention with some vomiting. On the fifth postoperative day the patient died suddenly from what was thought to be a massive pulmonary embolus.

CASE 5—B M L, a physician, aged 44, was referred to Dr C G Mixter complaining of generalized abdominal cramps and nausea of forty-eight hours' duration. He had had bilateral inguinal hernia for many years. Eighteen years previously bilateral herniorrhaphy was performed with recurrence on the right side. During the past four years he had worn a tight fitting truss. The hernia had become scrotal shortly after its recurrence but had always been reducible. Forty-eight hours before admission to the hospital, the hernia slipped down. He reduced it without any undue force, and thereafter the truss was able to retain it. Shortly afterward he began to feel nauseated and vomited. The nausea and the vomiting persisted, and the abdomen became distended. He began to experience cramplike pain about the umbilicus.

The abdomen was distended and tender over the lower half. The right inguinal region showed a distinct defect, with a slight impulse transmitted on coughing. Just above the usual site of the internal inguinal ring was a deep tender mass.

Operation through a herniorrhaphy incision revealed a large hernial sac displaced upward in a preperitoneal position and containing a loop of gangrenous small bowel. The intestine was resected and the hernia repaired. The convalescence was uneventful, except for a transient attack of biliary colic.

COMMENT

A hernia reduced *en masse* consists in a displacement of the sac and its contents into an anomalous position. Despite the apparent reduction, the relation of the sac to its contents remains undisturbed. The common pos-

tion that the sac assumes is the space between the peritoneal and the muscle layers of the abdominal wall ordinarily defined as the properitoneal space. Certain conditions must obtain before such a situation can occur. The neck of the sac must be sufficiently wide to allow the entrance of bowel or omentum and yet narrow enough to imprison and retain incarcerated contents. The sac itself must be sufficiently mobile within the hernial canal to permit it to be forced upward and inward. Likewise sufficient mobility of the neck of the sac, together with the parietal peritoneum immediately surrounding the hernial ring, is necessary to provide room behind the peritoneum for the "reduced" hernia. The structures surrounding the neck of the sac must be fairly well separated from the internal ring. The degree of mobility of the neck of the sac determines to a large extent the position which the falsely reduced mass will occupy. The neck may be fixed, but the peritoneum just within the peritoneal cavity and anterior to the ring may be so lax as to form a properitoneal pouch. Under such circumstances the "reduced" mass will occupy a properitoneal position and may then be palpable as a tumor in the abdominal wall. Similar laxity posterior to the ring may act to produce a retroperitoneal displacement of the sac. If considerable pressure and taxis are applied, rupture of the sac may occur and the incarcerated contents may come to lie extraperitoneally. Commonly the neck of the sac moves directly inward with the reduced sac and is therefore found projecting into the abdominal cavity. If omentum is adherent to the sac, the entire sac may be pulled inward when the patient lies down, since the omentum in sliding back tends to invert the sac.

Obviously, only a fairly large well developed hernia could provide these conditions. The wide indefinite ring of the direct inguinal type of hernia should not provide suitable circumstances for reduction *en masse*. Nevertheless this has been observed. The hernia whose contents have become permanently incarcerated is unlikely to be reduced *en masse*. In this case the sac is usually too firmly adherent. However, even here the possibility is not too remote. It is the moderate sized well established freely movable hernia lying in a canal whose walls are lax and distensible that is the most common type in which this accident occurs.

In the femoral hernia, reduction *en masse* is extremely rare, since the slitlike opening of the saphenous space with its firm fascia and sharp semilunar upper edge prevents the pushing of the sac and its contents inward beyond it. It is for the same reason that incarceration in femoral hernias is common. Despite this peculiar anatomic arrangement, actual reduction *en masse* with strangulation of bowel has been observed (case 1).

When reduction *en masse* occurs, it is usually possible to elicit the following story. The patient has invariably been aware of a hernia which had previously been reducible and on this occasion the hernia had apparently been reduced. Yet the pain, cramps and vomiting had continued or had appeared for the first time. The reduction need not necessarily have been accomplished with any undue force although the false reduction usually does occur as a result of an over-strenuous attempt at reduction by pressure or taxis, either by the patient by his friends or even by his physician. An ill fitting truss may provide the means for bringing about this accident. In a small percentage of cases the reduction occurs spontaneously and may take place several days or even weeks before the symptoms of intestinal obstruction have supervened.

On examination there may be noted the objective evidence of intestinal obstruction. Superficially the local examination may reveal nothing remarkable, but with careful palpation of the hernial canal through the ring there is to be detected a definite defect with only a feeble impulse on coughing. This finding is characteristic, and when it exists in any individual giving a history of a previous hernia a reduction *en masse* should be considered. In a properitoneal reduction, a mass may be felt in the abdominal wall above or medial to the usual site of the "reduced" hernia. Rectal examination usually fails to disclose anything of significance.

The treatment is immediate operation. The abdominal approach to the hernia is recommended as the most advisable since it is always necessary to incise the neck of the sac in order to liberate the bowel or omentum. The approach provides the most direct method of reaching and dealing with the various hernial orifices. In the event that resection of bowel is necessary, the advantages of doing so through a laparotomy incision are obvious. A lower rectus incision retracting the muscle medially should be the incision of choice. The inguinal, femoral and umbilical rings should be palpated first, and no attempt to pull forcibly the bowel or omentum out of the sac should be made. Time will be saved and trauma avoided if the neck of the sac is immediately cut and the contents are gently reduced back into the abdominal cavity. When the sac has been emptied and appropriate disposition made of its contents, it can be dealt with by inverting it into the abdominal cavity, and then amputating it after transfixion at the neck. If the patient's condition is good it may be advisable to repair the hernial canal through a separate incision. This procedure can be carried out with dispatch if the sac has been eliminated from within through the abdominal incision.

SUMMARY

Five cases of hernia reduced *en masse* were seen. Although this is considered a rare accident, three of the five cases occurred in a group of seventy-three incarcerated or strangulated hernias. It is shown to occur in the well established hernia with the sac lying loosely in the hernial canal. The hernial sac and its contents can be displaced properitoneally, retroperitoneally, or directly into the abdominal cavity. Forceful attempts at reduction may or may not be a factor in its production.

Patients are seen because of intestinal obstruction, and examination reveals a definite defect at the usual site of the hernia, with no apparent hernial sac. In the properitoneal false reduction a tumor mass may be felt in the abdominal wall above and medial to the site of the internal inguinal ring. The abdominal approach to the hernia is recommended as the most expedient.

330 Brookline Avenue.

Born Calcium Poor—To be normal and healthy the full-grown human body must be richer in calcium than in any other mineral element. Yet every human being is born calcium poor.

Why are we born calcium-poor? It is a handicap which nature accepts (or imposes) in order to diminish the casualties of delivery. Once the danger of the event of birth is safely past it is presumably to the advantage of the young organism to recover from the handicap of its low-calcium condition of body as rapidly as possible. Hence the extreme importance of liberal calcium intake for the growing child—Sherman H. C. Food and Health, New York, Macmillan Company, 1934.

Clinical Notes, Suggestions and New Instruments

CAYO POWER INSTRUMENTS

E. P. CAYO M.D. SAN ANTONIO TEXAS

These instruments are intended to cover the entire field of bone surgery and to do it in such a manner that, from the standpoint of antiseptis, they need cause no more anxiety than would ordinary hand instruments.

There is a set of these instruments, consisting of two cross cut saws (or reciprocators), an automatic chisel and a drill, or rotator, also several attachments and many tips, such as saw blades, drills and chisel blades. These instruments are

Fig 1—Reciprocator (saw gun) equipped for amputations or bone splicing

driven through a flexible shaft and by means of a Universal Motor permanently housed in a carrying case.

With these instruments any kind of saving imaginable can be done, and done without danger, because the hand can be closed on the teeth of the saw when it is going at full speed and yet with no danger to the hand. That is why ribs may be severed without injuring the pleura, or bone flaps made in the

Fig 2—Reciprocator equipped for stab sawing that is for starting to saw directly into the bone for the making of bone grafts curved or otherwise laminectomies and so on

skull without injuring the dura. Bone grafts may be cut, curved or otherwise. Laminectomies can be done with ease in a very short time. The instruments are particularly adapted for amputations and bone steppings. Saw blades, varying from slender keyhole saws to the stout bevel pointed stab saw, come with the instruments.

Stab sawing is a method of sawing that enables one to cut right down squarely into the bone to make grafts curved or otherwise, to do laminectomies, and to remove odd-shaped pieces of bone and the like. To do it well, however, requires considerable practice.

The automatic chisel consists of an attachment that converts the reciprocator into an automatic chisel. The attachment takes gouge and chisel blades of varied size and shape. With this instrument very delicate or very rapid work can be done.

The rotator (drill gun) is devised to operate any kind of bone cutting instrument requiring a rotary motion, such as drills, burrs, trephines and circular saws. It is built on the order of the reciprocator and is often referred to as a drill gun. Probably its most interesting feature is a gage that

Fig 3—Reciprocator with chisel attachment.

only controls depth of perforation but also fixes the drill point to the exact location on the bone where perforation is desired.

The flexible shaft, although very small and flexible, will still the powerful motor without breaking. It can be instantly connected to or disconnected from any of its instruments.

Fig 4—Rotator (drill gun) equipped with drill gage.

These instruments are built of chromium-plated bronze and stainless steel. They can be repeatedly sterilized without injury. They come in a carrying case 8 by 8 by 16 inches. The weight all told is about 25 pounds.

Fig 5—Instantaneous shaft connection.

It is sincerely hoped that these inventions and adaptation by their simplicity and versatility, their freedom from physical danger to both patient and operator, and last, but not least, their freedom from danger of field contamination will make the use of power instruments in bone surgery as popular as they should be.

Therapeutics

THE THERAPEUTICS OF THE COOK COUNTY HOSPITAL

EDITED BY BERNARD FANTUS, MD
CHICAGO

NOTE.—In their elaboration, these articles are submitted to the members of the attending staff of the Cook County Hospital by the director of therapeutics, Dr Bernard Fantus. The views expressed by various members are incorporated in the final draft for publication. The articles will be continued from time to time in these columns. When completed, the series will be published in book form.—Ed

THE THERAPY OF JAW FRACTURES AND OF FACE INJURIES

OUTLINE BY DR. J E SCHAEFFER AND DR. M B SKINNER

Fractures of the jaw are either traumatic or pathologic. External blows, gunshot wounds, automobile accidents, falls, and extraction of teeth are the most common traumatic causes. The most common pathologic conditions that predispose to fracture are carcinoma, sarcoma, cysts, osteomyelitis, tuberculosis and syphilis. Pathologic fractures are relatively rare.

DIAGNOSIS

As fractures of the jaw are many times overlooked and loss of function or deformity often results from failure to recognize them, a thorough examination of the jaws should be made and roentgenograms taken whenever a patient presents himself with a history of trauma and pain or swelling about the face.

One should look for

- 1 Local trauma
- 2 Abnormal mobility
- 3 Partial or complete loss of function
- 4 Crepitus
- 5 Deformity
- 6 Loss of occlusion in some part of the arch.
- 7 X-ray evidence

A fracture of the maxilla is more difficult to diagnose than that of the mandible. It may not be possible to obtain roentgenograms showing clear detail.

Differentiation Between a Fracture and Dislocation

—In a dislocation the patient is unable to close the jaws and cannot bring any of the teeth into occlusion. In a fracture some of the teeth may be in occlusion or can be brought into occlusion by manipulation of the fragments.

TREATMENT

General Principles —In most cases the earlier the reduction is made the better, for the sooner the fragments are brought into position and immobilized the sooner the repair can begin. If, however, the patient is so severely injured that his life is in danger, it is better to delay treatment of the jaw until he is on the way to recovery, even as long as three or four weeks. If there is a marked swelling of the floor of the mouth or if the tissues on the lingual surface or tongue are badly injured, immediate fixation may embarrass respiration or favor infection.

After the jaws have been fixed, the patient should be instructed to cleanse his mouth thoroughly after each feeding. This is best accomplished by the use of a "baby sized" tooth brush and a dentifrice followed

by rinsing the mouth with some good antiseptic, e. g., the Antiseptic Solution of the National Formulary. The patient has to subsist, of course, on a liquid diet. It is never necessary to extract a tooth in order that the patient may take nourishment. Even when there is a full complement of teeth there is enough space between the teeth to draw liquid through.

As practically all fractures of the jaw, when teeth are present, are compound, they are susceptible to infection. Some advocate establishing immediate drainage of all fractures by an incision just below the fracture line. A more conservative plan is to take care of the infection when it develops. When it does occur fomentations are applied, and, when localization takes place an incision is made to the bone and drainage instituted.

The Barton bandage, commonly applied either as a temporary or as a permanent means of treating a jaw fracture, is inefficient when there is any displacement. In most cases it tends to produce more displacement and causes more discomfort than no treatment.

Reduction and retention require recognition of the following special types of injury.

Fracture of the arch

- Complete transverse fracture of the maxilla
- Fracture of the arch in the edentulous
- Fracture back of the last molar tooth
- Fracture through the neck of the condyle.
- Extensive fracture of the maxilla
- Lacerations about the face and mouth.

FRACTURE OF ARCH

When there are a considerable number of teeth present in both arches, the reduction and fixation of a fracture is greatly simplified, as the opposing arch may be utilized to fix the jaw in its proper relation by the use of intermaxillary wires. The methods commonly used are (a) the first Gilmer, (b) the second Gilmer, (c) the loop method and (d) the Hammond splint.

(a) In the first Gilmer method (fig 1) a No 24 gage brass wire, which is very pliable and does not stretch, is used. The wire is cut into lengths of about 15 cm each, the ends being cut on a slant, which makes it easier to pass them through the interproximal spaces. The wire is then passed, from the lingual surface, through the interproximal spaces on each side of the tooth to be utilized for fixation. With a blunt instrument the loop of the wire on the lingual surface is held well down on the neck of the tooth and the two ends are grasped with a large needle holder and the wire is twisted tightly about the tooth. It is important that the wire should be down on the neck of the tooth to prevent it from slipping. A sufficient number of teeth are wired on either side of the line of fracture, and the corresponding teeth of the opposing jaw are wired in the same way. The mandible is then fixed to the upper jaw by twisting the wires of one to those of the other. By crisscrossing the upper and lower wires, a more stable fixation may be obtained.

There is one disadvantage in this method. In order to open the mouth the wires have to be cut, and if union has not taken place it is then necessary to rewire the jaws.

(b) In the second Gilmer method (fig 2) a heavy arch wire, 14 gage, is adapted to the buccal and labial surfaces of the teeth of both arches. These are attached by threading a No 24 gage brass wire between and around the teeth. Care should be taken that the wire is well down on the neck of the teeth and that a suffi-

cient number of teeth are wired to hold the arch wire rigid. Intermaxillary wires are then placed around the arch wires and the jaws are brought into occlusion by twisting them up tightly. This method is advantageous in that the mouth may be opened and inspected at any time and fixation again be established by merely replacing the intermaxillary wires. It is a much more

stable method, which makes it very useful in cases of delayed union.

Another adaptation of the Gilmer arch bar is very useful in handling fractures difficult to reduce, such as those in which there has been a delay in treatment. A modification of the arch bar is made by either

Fig 1—First Gilmer method

bending a series of loops or soldering a series of lugs to both the upper and lower arch bars (figs 3 and 4). These lugs are directed away from the occlusal line of the teeth. Elastic bands are then placed over the lugs and distributed in such a manner as to bring traction in the right direction for the reduction of the displaced fragments. The constant and even pull soon brings the fragments into their proper alignment with little or no discomfort to the patient.

(c) The loop method (fig 5) is one in which a strand of No 24 gage wire is twisted in the middle to form a loop large enough for another wire of the same size to pass through. The ends of this wire are then passed between the two teeth to be ligated from the buccal to the lingual side. One wire is brought around and passed through the interproximal space on the distal side of one tooth, the other is passed through on the mesial side of the adjacent tooth. One strand is passed through the eyelet and the two ends are then twisted, the wires being pulled tightly against the teeth. The same teeth in the opposing arch are wired in a like manner. The number of teeth wired depends

on the kind and location of the fracture. Intermaxillary wires are now passed through the eyelets and the teeth brought into occlusion and the wires twisted tight.

This method is not as stable as the second Gilmer method nor does it meet the variety of uses. Its one ad-

Fig 2—Second Gilmer method

vantage is that it is easily and quickly applied and the jaws may be opened and inspected and fixation again obtained by merely placing on new intermaxillary wires.

Bringing the teeth into occlusion is not always as simple as just merely tightening the intermaxillary wires. In many cases some manipulation is necessary. This is strictly a mechanical problem and depends on

the amount of displacement and the direction of the line of fracture. The amount of displacement will depend on the direction, application and degree of force producing the fracture plus muscular pull. In a general way one might say that the short fragment is displaced upward and the long fragment has a tendency to be displaced in a downward direction.

(d) The Hammond splint (fig 6) furnishes another satisfactory method of handling single fracture of the mandible when there are sound teeth in both fragments. This splint consists of two arch wires, No 14 gage, one shaped to the teeth on the buccal surface and the other on the lingual surface. These are wired together with No 24 gage brass wires by passing them through the interproximal spaces and around the teeth. The small wires are passed over one arch wire and under the other and then twisted tight. This method allows the patient full movement of his jaw and saves him the inconvenience of having his jaws immobilized for several weeks.

COMPLETE TRANSVERSE FRACTURE OF MAXILLA

A complete transverse fracture of the maxilla requires fixation outside the mouth. The jaws are wired together by the second Gilmer method. A skull

Fig 3—Adaptation of second Gilmer method for delayed reduction

cap of plaster or the crown part of a woman's felt hat is adjusted to the head and both jaws are then immobilized by a piece of rubber dam with a slight tension on it, encircling the mandible and attached to the skull cap. When there is considerable displacement of the maxilla it is often necessary to reduce it by rubber band traction.

If this is the case, it is sometimes unavoidable to delay the fixation of both jaws until the teeth are brought into proper occlusion, as these may act as a wedge and prevent the traction from bringing the jaws into proper relation. Immobilizing the mandible to the maxilla is not always possible, as the fracture through the nasal fossae may obstruct breathing. In these cases the maxillae and facial bones are supported by a Kingsley splint (fig 7). This is constructed to cover the upper teeth with metal arms extending outside the mouth and backward in line with the occlusal plane (fig 7A). This permits using the top of the skull as a fulcrum in order to seat the fractured bones somewhere near their normal relationship. After the maxillary bones have been seated, pressure is applied to the mandible externally in order to establish normal occlusion (fig 7B).

FRACTURES OF THE ARCH IN THE EDENTULOUS

With slight displacement, not great enough to cause nonunion or deformity, the only treatment necessary is to advise a soft diet and rest. These cases as a rule get along well and, when union has taken place, any change in the relationship of the two arches may be corrected by the proper construction of artificial den-

tures If the displacement is extensive, it may be reduced by direct or circumferential wiring

In the direct wiring method an incision is made along the lower border of the mandible The line of fracture is exposed and all soft tissue removed from between the ends of the bone Two holes are drilled in each fragment, one above and one below the mandibular canal Two silver wires, 20 and 22 gage, are placed through the holes as follows The first wire is inserted through the upper opening in the short fragment to the lower hole in the long fragment and then the other wire is placed in the other holes The fragments are adjusted and the wires tightened to hold the fragments in their proper position Care should be taken that the ends of the wires do not stick out into the soft tissue to cause undue irritation The wound is sutured and the patient should be kept under close observation the first week to detect onset of infection promptly If no infection occurs, the wires are left in permanently If, on the other hand, infection occurs, it may be necessary to remove the wires for complete healing to take place, but this should not be done early, as it is possible for union to occur in the presence of a low grade infection

When the circumferential wiring method is used, an incision is made as before and two wires are passed up into the mouth close to the bone on the buccal and lingual surface, one wire on each side of the line of fracture The ends of the wires are passed through holes in a lead or vulcanite plate, which has previously been fitted to the ridge, and tightened up The wound is then sutured This method is not as stable as the direct

Fig 4—Angle bands with hooks and rubber bands for delayed reduction

wiring but it saves the necessity of drilling into the bone and thus lessens the danger of infection

Fractures in which there has been a considerable loss of bone may require some type of dental splint As each case is an individual problem and the construction of the splint requires the technical skill of a dentist, a detailed discussion is not advisable here It is necessary to treat many of these by means of a bone graft

FRACTURE BACK OF LAST MOLAR TOOTH

Fracture of the jaw back of the last molar tooth is very difficult to handle If the fracture line is in a downward and backward direction there will be an upward and lateral displacement of the short fragment caused by the action of the temporal, masseter and internal pterygoid muscles When this occurs there is a marked deformity of the jaw with a loss of the normal angle of the mandible Many methods have been devised to treat this type of fracture, but none have proved entirely satisfactory One method was to place a modeling compound or gutta percha mold in this area and then wire the jaws together This, however, makes it very difficult to keep the mouth clean in this area and tends to infection It generally causes a

pressure necrosis of the soft tissue Another method is to make a splint with a pin fixed in the ramus and force the posterior fragment into position by means of a jackscrew Similar to this is the use of a head cast with a rod extending downward to the back of the neck The angle of the jaw is exposed, a hole drilled through the bone, and a wire passed through and fastened to the rod of the plaster cast

Fig 5—Loop method

A method which was introduced by the Oral Surgery Department at the Cook County Hospital, and one which seems most satisfactory, is as follows Arch wires are made as in the second Gilmer method, except that a prolongation of the unannealed wire is extended back past the line of fracture The end of this extension wire is forked to fit over the bone on the short fragment It is then bent in such a way that, when the jaws are brought into occlusion and fixed, the short fragment will be held down in position In the last two years about forty cases have been treated this way with good results None have shown any injury to the bone where the wire has rested against it It is relatively simple to apply and the risk of infection caused by drilling into the bone is eliminated

FRACTURE THROUGH NECK OF CONDYLE

In fracture through the neck of the condyle the general surgeon usually suggests an open reduction or the removal of the condyle Both of these are contraindicated because of the danger of such an operation The facial nerve lies just external to this region and unless the greatest care and skill are used it is apt to be injured, thus causing paralysis to that side of the face Another great danger in this type of operation is the fact that the internal maxillary artery lies below the neck of the condyle, and if it is severed or injured it is difficult to control the hemorrhage Wiring the teeth into occlusion usually establishes a satisfactory relationship of the long and short fragments

Fig 6—Hammond splint modified

Fractures treated this way have united with satisfactory function, ankylosis of the temporomandibular joint has not occurred

EXTENSIVE FRACTURE OF MAXILLA

Extensive fractures of the maxilla, involving the other facial bones, fall chiefly into two classes according to the character of the predominant displacement "If a severe force, such as a kick of a horse, is applied from in front in an upward and backward direction,

COUNCIL ON PHYSICAL THERAPY

JOUR. A. M. A.
Nov. 23, 1933

the maxilla may be driven in toward the base of the cranium with considerable comminution and impaction, or if, as is most commonly the case, the malar bone will be to the prominence of the cheek, the maxillary antrum, but at more or less driven into the maxillary antrum, but at the same time there may be extensive radiating frac-

Fig. 7—Kingsley splint

tures If one of these is a transverse fracture through the orbits, the whole bony framework of the face may sag down, supported only by the soft tissue" (Blair) The general principles of treatment of such injuries are as follows If depressed fractures of the maxilla or nasal bones are present, these must be elevated back into position, lacerations of the soft tissue are cleaned and sutured so as to have the injured tissue brought back as near as possible to the normal position All scars are allowed to heal for at least six months, as an ugly scar tends to become less unsightly If after six months one believes that the scar can be improved, it is carefully resected for cosmetic appearance

Fractures of the malar bone, when this bone is driven into the maxillary sinus, show a marked depression on the injured side of the face Often the patient will complain of difficulty in closing his jaws, as the coronoid process of the mandible is impinged on by the depression of the zygomatic arch These cases are treated by making an incision in the buccal sulcus and exposing the fractured maxilla The malar bone is then elevated into position through the maxillary sinus and held in place by packing the sinus with gauze

LACERATIONS

Lacerations about the face and the mouth frequently accompany fractures of the jaw When the laceration extends from the external surface through to the mouth, treatment should be as follows The wound is thoroughly cleansed with green soap and water then irrigated with sterile water, and the surrounding tissue swabbed with alcohol The mucous membrane is sutured from the inside of the mouth with black silk, so that the stitches may later be easily removed Lacerations in the oral cavity heal more quickly if the raw surfaces are loosely approximated than if left to heal by themselves The deep tissues are then sutured with 0000 catgut Then the skin surfaces are brought together with horsehair

When the laceration extends through the lip it is important that the vermilion borders be sutured together in a straight line, otherwise an ugly scar will result

In cases in which there has been considerable loss of tissue, it is best to bring the tissues as near to their normal relation as possible, with the idea of a plastic correction later, though at times a plastic operation may with advantage be undertaken immediately, as was done in a patient who had three fourths of his upper

lip and the floor of his nose bitten off Both alae of the nose were pulled laterally, which caused much deformity In this case a piece of the mucous membrane of the mouth was brought up and sutured in to form the part of the missing floor of the nose The edges of the remaining portion of the lip were then straightened with a scalpel and sutured together A Logan face bow was applied to keep tension off the sutures The wound has healed well, leaving the mouth less than one-third its normal size This, however, was easily corrected by V incisions at the corners of the mouth

In lacerations of the lips, an infra orbital injection for the upper, and a mental injection of 2 per cent procaine solution for the lower, will often save the patient much pain and make it much easier for the operator to work

When patients present lacerations which have street dirt in them, a prophylactic dose of 1,500 units of tetanus antitoxin is always given

NOTE—To improvise a cheek retractor, bend the handle of a spoon Set the bowl of the spoon against the patient's cheek and retract the cheek by pulling on the handle and attach the handle to the back of the neck with adhesive tape Such an improvised retractor makes it possible to do some of this work without assistance

Council on Physical Therapy

THE COUNCIL ON PHYSICAL THERAPY HAS AUTHORIZED PUBLICATION OF THE FOLLOWING REPORTS
HOWARD A. CARTER Secretary

LIEBEL-FLARSHEIM (SW2-C) SHORT WAVE GENERATOR ACCEPTABLE

Manufacturer The Liebel-Flarsheim Company, Cincinnati. This unit is recommended by the manufacturer for medical diathermy and for minor electrosurgery It is well constructed. The wavelength is about 25 meters It is equipped with two 125-watt vacuum tubes and operates from a 60 cycle alternating current. The power input is about 550 watts. Since there is no acceptable method for measuring the output of diathermy machines, this value is not stated. Its shipping weight is about 150 pounds.

Fig. 1—Liebel Flarsheim generator (SW2 C) Short Wave Gen

Either pad electrodes or a coil for electromagnetic induction may be used. The unit is cooled by a motor-driven forced draft fan. Operating this unit under full load indicated that the temperature rise of the transformer and the cabinet was within the temperature limits considered safe by the Council. At the request of the Council, the Liebel-Flarsheim Company submitted data concerning the tissue heating effect in the human thigh. The firm reported that four turns of the induction cable two turns being above and two below the point of insertion of the inductive Thermocouples were applied to the thigh and deep-lying tissue (quadriceps extensor) After twenty five minutes' treatment, the machine being operated at the patient's tolerance the temperature rise, with the coil technique was observed to be more than that obtained with conventional diathermy—the criterion for investigating short wave machines which the Council has adopted In a clinic acceptable to the Council, the firm's report was confirmed

Burns may be produced by this machine, but with the observance of ordinary care, they may be avoided, their likelihood to occur is much less than with the use of conventional diathermy.

The machine was used by the Council's investigator in a clinic for several months, and he reported that it gave satisfactory service.

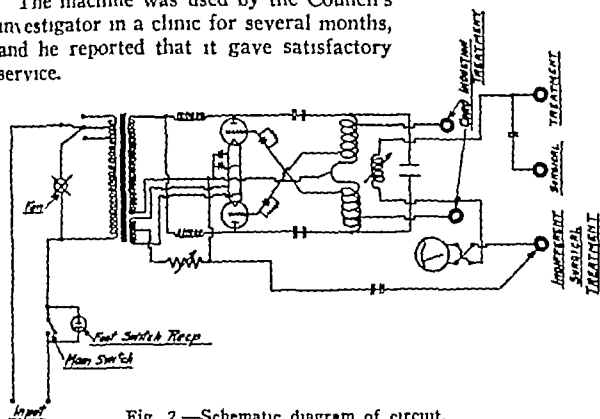

Fig 2—Schematic diagram of circuit.

In view of the foregoing report, the Council on Physical Therapy voted to include the Liebel-Flarsheim (SW2-C) Short Wave Generator in its list of accepted apparatus.

McINTOSH UNIVERSAL DIATHERMY UNIT ACCEPTABLE

Manufacturer McIntosh Electrical Corporation, Chicago

The manufacturer recommends this unit for medical and surgical diathermy. It is a cabinet model. The main line switch is mounted on the panel. The binding posts for the treatment cords are mounted on the front of the panel, and a four-gap spark gap covered by a metal screen is mounted on top. It has a four point "voltage selector switch" (rheostat) and a typical milliamperemeter, protected by fuses, with two scales, 0 to 1,000 and 0 to 4,000. There is a spiral coil mounted on a rotating rod in such a manner that the frequency in kilocycles is said to be altered from approximately 750 to 2,200. The unit weighs about 100 pounds.

At the request of the Council, the manufacturer submitted data containing a report of tests of the unit for power input and output, and for its spark gap and transformer temperature rise. The results recorded in the data were in agreement with the observations of the Council's investigator, and in conformity with the standards for diathermy machines previously established by the Council.

The Council's investigator reported that, from a clinical standpoint the machine is a satisfactory device for ordinary

Fig 2—Schematic diagram of circuit.

local medical diathermy and for electrodesiccation and electrocoagulation.

In view of the foregoing report, the Council voted to include the McIntosh Universal Diathermy Unit in its list of accepted apparatus.

REPORTS OF THE COUNCIL

THE COUNCIL HAS AUTHORIZED PUBLICATION OF THE FOLLOWING REPORT
PAUL NICHOLAS LEECH Secretary

GLUTAMIC ACID

A brand of glutamic acid was presented to the Council for consideration as an agent to be used in the treatment of myasthenia gravis and muscular dystrophy (progressive or pseudohypertrophic) and as generally interchangeable with aminoacetic acid N R.

The Council considered the relative therapeutic value of aminoacetic and glutamic acids, and, in the light of this whether or not the latter is a nonessential product. The usefulness of certain amino acids in the treatment of these myopathies has been largely demonstrated with aminoacetic acid. Tripoli and his associates¹ are the only workers who have used glutamic acid for this purpose. They claim that it cost less than half as much as aminoacetic acid, they believe that it is a slightly superior creatine former and even less toxic (in animals) than the relatively harmless aminoacetic acid. Further studies by these workers² suggest that its efficacy is equal to that of aminoacetic acid.

Brand, Thomas, Milhorat and Technor,³ however have shown that there is no increase in creatinine demonstrated by patients with progressive muscular dystrophy when glutamic acid is administered. The Council has been informed that Shorr and Richardson in an article to be published will report confirmation of this finding. There appear to be no adequately controlled observations indicating that glutamic acid is of therapeutic value in muscle disease. Commercial prices at present do not indicate that this is a cheaper agent. The Council doubts the advisability of administering from 20 to 30 Gm daily of this fairly strong organic acid, being of the opinion that it would be irritating to the stomach.

As a result of its consideration, the Council decided that there is not available sufficient confirmed, controlled evidence of the usefulness and harmlessness of glutamic acid to warrant acceptance at this time for inclusion in New and Nonofficial Remedies. A statement of the Council's consideration was sent the manufacturer of the submitted brand on receipt of which the firm agreed to close active promotion of its brand. In the interest, however of those who desire to know the Council's attitude on glutamic acid, publication of the foregoing statement was authorized.

NEW AND NONOFFICIAL REMEDIES

THE FOLLOWING ADDITIONAL ARTICLES HAVE BEEN ACCEPTED AS CONFORMING TO THE RULES OF THE COUNCIL ON PHARMACY AND CHEMISTRY OF THE AMERICAN MEDICAL ASSOCIATION FOR ADMISSION TO NEW AND NONOFFICIAL REMEDIES. A COPY OF THE RULES ON WHICH THE COUNCIL BASES ITS ACTION WILL BE SENT ON APPLICATION.

PAUL NICHOLAS LEECH Secretary

CONCENTRATED SOLUTION LIVER EXTRACT PARENTERAL-LEDERLE—A sterile, aqueous solution, containing the nitrogenous nonprotein fraction G of Cohn et al obtained from fresh mammalian liver, preserved with 0.5 per cent of phenol. Each cubic centimeter contains antianemic substance obtained from 100 Gm of liver.

Actions and Uses—Concentrated solution liver extract parenteral-Lederle is proposed for intramuscular injection in the treatment of pernicious anemia and sprue.

Dosage—To insure optimum dosage for cases of pernicious anemia in relapse it is advisable to make an injection of 1 cc. each day for three or four successive days. In a series of cases

¹ Tripoli, C. J. and Beard, H. H. Muscular Dystrophy and Atrophy. Arch. Int. Med. 53: 435 (March) 1934.

² Tripoli, C. J., McCord, W. M. and Beard, H. H. Muscular Dystrophy. Muscular Atrophy. Myasthenia Gravis and Strabismus. J. A. M. A. 103: 1595 (Nov. 24) 1934.

³ Brand, E., Harris, M. M., Sandberg, M. and Ringer, A. T. Studies in Origin of Creatine. Am. J. Physiol. 90: 296 (Oct.) 1929. Milhorat, A. T., Technor, Fritz, and Thomas, Karl. Significance of Creatine in Progressive Muscular Dystrophy and Treatment of This Disease with Glycine. Proc. Soc. Exper. Biol. & Med. 20: 609 (Feb.) 1932.

in which remissions have been thus initiated by the use of concentrated solution liver extract parenteral-Lederle there is evidence that injections of 1 cc every two weeks provide sufficient active material to complete the remission and maintain a satisfactory blood picture. In complicated cases and those with extensive neurologic involvement, the optimum dosage may be much larger and must be determined for each patient.

Manufactured by the Lederle Laboratories Inc., Pearl River N. Y.
Vials Concentrated Solution Liver Extract Parenteral-Lederle 1 cc

Concentrated solution liver extract parenteral-Lederle is prepared as follows: A mixture of finely ground liver and water is acidified to the isoelectric point pH 5.054. After partial coagulation of the liver proteins is effected by heating to 75-85°C the pulp is separated by filtration centrifugation or pressing and the aqueous filtrate is concentrated in vacuo to the consistency of a thin syrup. By careful fractional precipitation with large volumes of alcohol at low temperatures (4°C) much inactive material (proteins) is precipitated and subsequently discarded. The alcoholic filtrate is concentrated in vacuo and sufficient alcohol added to precipitate the active material (fraction G) of Cohn et al. (Proceedings of the American Society of Biological Chemistry *J. Biol. Chem.* 74:1619 [July] 1927). The washed precipitate generally known as Cohn's fraction G, commonly obtained as a hygroscopic brownish powder in addition to the active antianemic factor, contains much inert matter. In order to obtain a concentrate of the active factor as free as possible from inert substances the solution containing the fraction G of Cohn is treated with a special activated carbon. Subsequently the material is concentrated in vacuo so that each cubic centimeter represents material obtained from 100 Gm of liver. The solution is then sterilized and 0.5 per cent of phenol added as a preservative.

FERRIC CHLORIDE—For description see the U. S. Pharmacopeia and Useful Drugs under *Ferri Chloridum*.

Saf-T-Top 5% Ferric Chloride in 50% Glycerine Solution. A solution of ferric chloride 5 per cent in glycerin 50 per cent marketed in ampules having a capillary opening and containing 2 and 15 cc. This form is intended for use as a neutralizing agent of the toxicodendrol of poison ivy and poison sumac. It is applied externally.

Prepared by Robert A. Bernhard, Rochester N. Y.

NOVOCAIN (See New and Nonofficial Remedies, 1935, p. 63, and THE JOURNAL, June 22, 1935, p. 2256).

The following dosage forms have been accepted:

Sterile Ampules Novocain Crystals for Spinal Anesthesia 500 mg
Sterile Ampules Novocain Crystals for Local Anesthesia 500 mg

ISOPROPYL ALCOHOL—Propan-2-ol— $\text{CH}_3\text{CH}(\text{OH})\text{CH}_3$ —obtained by the reduction of acetone or, as a product in the petroleum industry, by the absorption of olefin gases containing propylene in sulphuric acid, and hydrolyzing the resulting sulphuric acid esters.

Actions, Uses and Dosage—Isopropyl alcohol, because it is a solvent for creosote, is used in the removal of that substance from the skin as a prophylactic agent against creosote burns. Isopropyl alcohol has been recommended for the disinfection of the skin and of hypodermic syringes and needles. As it is said not to affect the potency of solutions of insulin, it has been employed as a disinfecting agent in connection with the administration of this agent. Until further data are available isopropyl alcohol should not be relied on to destroy such spore-bearing organisms as *Clostridium tetani*, *Clostridium Welchii* or *Bacillus anthracis*. It is not potable and should not be given by mouth.

Isopropyl alcohol is a clear colorless volatile liquid having a characteristic odor and a slightly bitter taste miscible with water in all proportions, also miscible with chloroform and ether. It is insoluble in salt solutions and may be recovered from aqueous mixtures by salting out with sodium chloride, sodium hydroxide, etc. Specific gravity at 25°C from 0.780 to 0.790. Refractive index at 20°C from 1.3770 to 1.3780. Isopropyl alcohol is volatilized at low temperatures and boils at from 81 to 83°C. It does not affect blue or red litmus paper previously moistened with water when diluted with an equal volume of water.

Shake 20 cc. of isopropyl alcohol in a glass stoppered cylinder with 1 cc. of a freshly prepared solution of ammonio silver nitrate and allow to stand in diffused daylight for six hours; the mixture does not become more than faintly opalescent or acquire more than a faint brownish tint (aldehyde). To 5 cc. of isopropyl alcohol add 2 cc. of normal sodium hydroxide solution and 5 drops of a 1 per cent aqueous solution of sodium nitroprusside mix thoroughly; finally make slightly acid with acetic acid; no purplish red color (aldehyde).

Evaporate 100 cc. of isopropyl alcohol in a platinum dish on a water bath and dry at 100°C; the residue does not exceed 0.01 per cent.

Saf-T-Top Isopropyl Alcohol 98%. Isopropyl alcohol 98 per cent marketed in ampules having a capillary opening and containing 2 and 15 cc. This dosage form is intended solely for the removal of creosote from the skin.

Prepared by Robert A. Bernhard, Rochester N. Y.

MERCUROCHROME (See New and Nonofficial Remedies 1935 p. 309).

The following dosage forms have been accepted:

Saf-T-Top Mercurochrome Solution (See New and Nonofficial Remedies, 1935 p. 312). Also marketed in ampules with a capillary opening, containing 15 cc. of the aqueous 2 per cent solution.

Prepared by Robert A. Bernhard, Rochester N. Y.

Saf-T-Top Mercurochrome 2 per cent in 25 per cent Glycerine. A solution of mercurochrome H. W. & D. 2 per cent in a solution of 25 per cent glycerin marketed in ampules with a capillary opening containing 2 and 15 cc.

Prepared by Robert A. Bernhard, Rochester N. Y.

RABIES VACCINE (See New and Nonofficial Remedies, 1935, p. 380).

Lee Laboratories, Columbus, Ohio

Rabies Vaccine Semple Method (Lee)—An antirabic vaccine prepared according to the general method of David Semple (phenol killed). The fixed virus of rabies is injected subdurally into normal rabbits. These rabbits show definite symptoms of rabic paralysis in from six to seven days. At the time of complete paralysis they are bled to death and the brain is removed aseptically. Necropsy shows the rabbits to be normal, and sterility tests are made on the brain tissue to insure freedom from bacterial contamination. Sterile brains are then emulsified in 1 per cent of phenol by shaking with pyrex glass beads. The emulsion is passed through a 100 mesh sieve, and the whole made to a 16 per cent emulsion, and heated at 37.5°C for twenty-four hours in the incubator in order to kill the virus. After removal from the incubator it is made to an 8 per cent emulsion by adding an equal volume of physiologic solution of sodium chloride. The finished product is an 8 per cent brain emulsion containing 0.5 per cent of phenol and 0.85 per cent of sodium chloride.

The finished product is tested for absence of living virus by injection into rabbits. Injections are also made into guinea pigs and mice to check against contamination with tetanus bacilli.

Rabies vaccine Semple method (Lee) is marketed in packages containing seven and fourteen 1 cc. vials respectively. All the doses are of the same potency, one dose (1 cc.) is to be given daily over a period of fourteen days.

Committee on Foods

THE COMMITTEE HAS AUTHORIZED PUBLICATION OF THE FOLLOWING REPORTS

RAYMOND HERTWIG Secretary

NOT ACCEPTABLE

- (a) LOEB'S GENUINE GLUTEN BREAD (FRESH)
(b) LOEB'S GENUINE GLUTEN BREAD SLICED AND TOASTED

Manufacturer—Loeb Dietetic Food Company, New York.

Description—(a) Gluten bread prepared from gluten flour, water, shortening, yeast and salt. The gluten flour contains on a water-free basis not less than 71 per cent nitrogen, not more than 56 per cent nitrogen-free extract (protein factor 57) and not more than 44 per cent starch as determined by the diastase method. (b) Toasted slices of the gluten bread.

Analysis (submitted by the manufacturer)—

| | per cent |
|--|----------|
| (a) | |
| Moisture | 24.9 |
| Ash | 2.5 |

| Carbohydrates other than crude fiber (by difference) | 36.1 |

Calories—(a) 31 per gram 88 per ounce
(b) 38 per gram 108 per ounce

Claims of Manufacturer—The package labels bear the claims "For Use in Restricted Diet under Directions of a Physician."

Two slices of Loeb's Genuine Gluten Bread contain less carbohydrates than a single slice of ordinary white bread. A booklet "Diabetes and the Restricted Diet" states that "this booklet [contains] a list of delicious recipes, all of which marked with an asterisk are suitable for the reducing diet. White bread, cakes and candies should be entirely discarded, and in their place Loeb's Sliced and Toasted Gluten Bread, and other starch-free and starch reduced foods should be consumed."

Uselessness as a Special Purpose Food—Loeb's Genuine Gluten Bread and Loeb's Genuine Gluten Bread Sliced and Toasted are manufactured specially for use in diets restricted in dextrose formers. To be eligible for acceptance, such type of bread and toast shall contain dextrose formers yielding dextrose in an amount not greater than 33 Gm per hundred cubic centimeters (the dextrose equivalence being computed as the carbohydrate, plus 58 per cent of protein, plus 10 per cent of the fat content of the food). Dextrose formers of these breads on the other hand yield many times 33 Gm of dextrose per hundred cubic centimeters.

There is authoritative evidence that commercially prepared special diabetic foods are of limited usefulness to the diabetic patient and that the availability of insulin makes them no longer necessary. Artificial substitutes for ordinary foods are not to be favored. It is much better for the diabetic patient to learn how to plan his diet with foods in common use and readily available. The diet should be exactly prescribed in carbohydrate, protein and fat and total calories.

The designation of a food as a 'diabetic food' merely because it is low in carbohydrates is now unwarranted and misleading and gives the erroneous impression either that the food taken in unrestricted quantities in diabetes is harmless or that it has remedial action. Except for the necessity of restricting foods to avoid overstepping the food tolerance, there are no special diabetic nutritional requirements. The exploitation of starch-free or low carbohydrate foods containing an excess of protein for use by diabetic patients is unwarranted. Protein may be tolerated almost as poorly, if not quite as poorly, as starch in diabetes.

These gluten breads have no specific reducing properties and are no more useful than ordinary white bread in special reducing diets. The caloric content is similar to that of usual bread. The fact that the starch content may be somewhat less than that of usual bread does not specifically qualify the products for a reducing diet.

Because Loeb's Genuine Gluten Bread and Loeb's Genuine Gluten Bread Sliced and Toasted are adjudged without usefulness or special adaptability for inclusion in diets for obesity or diets restricted in dextrose formers, they will not be listed among the accepted foods of the Committee on Foods.

ACCEPTED FOODS

THE FOLLOWING PRODUCTS HAVE BEEN ACCEPTED BY THE COMMITTEE ON FOODS OF THE AMERICAN MEDICAL ASSOCIATION FOLLOWING ANY NECESSARY CORRECTIONS OF THE LABELS AND ADVERTISING TO CONFORM TO THE RULES AND REGULATIONS. THESE PRODUCTS ARE APPROVED FOR ADVERTISING IN THE PUBLICATIONS OF THE AMERICAN MEDICAL ASSOCIATION AND FOR GENERAL PROMULGATION TO THE PUBLIC. THEY WILL BE INCLUDED IN THE BOOK OF ACCEPTED FOODS TO BE PUBLISHED BY THE AMERICAN MEDICAL ASSOCIATION.

RAYMOND HERTWIG Secretary

HULBURT'S BRAND CALIFORNIA ORANGE JUICE (SWEETENED)

Manufacturer—Hulburt's Fruit Products, Inc., New York.

Description—Canned pasteurized California Valencia orange juice with added sucrose retaining in high degree the natural vitamin C content.

Manufacture—Ripe standard grade Valencia oranges are washed, graded (inferior or defective fruit is removed) halved by machine and reamed by hand. The juice is screened to remove coarse pulp and rag, pasteurized in pipes at 82 C., and sealed in enamel lined cans. The equipment is monel metal or glass lined.

Sucrose is added in varying quantities to produce standard uniform sweetness.

Calories—0.5 per gram 14 per ounce

Vitamin—Chemical assay for cevitamic (ascorbic) acid shows the product to approximate fresh orange juice in vitamin C content.

Claims of Manufacturer—This canned orange juice retains in high degree the nutritional values of the natural fruit juice and is intended for all the dietary and table uses of orange juice.

TREESWEET BRAND CALIFORNIA LEMON JUICE

Manufacturer—TreeSweet Products Co. Los Angeles

Description—Canned California lemon juice largely retaining the natural nutritional values.

Manufacture—Juice is expressed from selected, tree ripened fruit processed and canned as described for TreeSweet Pure California Orange Juice (THE JOURNAL, June 15, 1935, p 2187)

| <i>Analysis</i> (submitted by manufacturer) — | per cent |

Calories—0.16 per gram 4.6 per ounce

Vitamin—Rich source of vitamin C

Claims of Manufacturer—No added sugar or preservative. The process used enables retention in high degree of natural food values.

HORMEL BRAND CHICKEN BROTH WITH RICE

Manufacturer—George A. Hormel & Co., Austin, Minn.

Description—Chicken broth with rice, salt and sugar and flavored with water extract of carrots, celery, onions and peppers.

Manufacture—The carrots are peeled by machine, pared by hand diced and washed. The celery is freed of root and leaves, and the separate stalks are cleaned by hand. The onions are peeled and chopped. The birds are singed and the pin feathers removed. The birds are inspected by government inspectors, the feet and heads are sawed off, the viscera are removed and the birds are washed and sawed into pieces. Hearts and gizzards are retained for the broth.

The birds with a definite quantity of carrots, celery, onions and peppers in muslin sacks are placed in the required amount of water, seasoned with salt and boiled under pressure for two hours at 230 F. The fat is skimmed off. The broth is screened and a given quantity filled into cans with definite amounts of rice and skimmed fat. The cans are sealed and processed.

JOHNSON'S BESTOVALL BRAND TOMATO JUICE

Distributor—H. A. Johnson Company, Boston and New York.

Packer—American Packing Corporation, Evansville, Ind.

Description—Pasteurized tomato juice with added salt, retains in high degree the natural vitamin content. The same as Loudon Brand Tomato Juice (THE JOURNAL, June 25, 1932, p 2289).

BOOKLET 'INFANT FEEDING WITH IRRADIATED EVAPORATED MILK'

Sponsor—Irradiated Evaporated Milk Institute, Chicago.

Description—Booklet for distribution to physicians only containing information on the preparation of irradiated evaporated milk, its nutritional advantages for the feeding of normal infants as well as its use under special conditions, such as prematurity, atresia, diarrhea and milk allergy. Detailed regular milk and acid milk formulas and lists of references to recent clinical literature are given.

MEDICAL LITERATURE AND MEDICAL LIBRARIES

The growth of medical literature and its applicability to the practice of medicine is one of the interesting historical phenomena associated with our profession. When printing with movable type was developed, all manner of learning received a mighty impetus. Because medicine is so close to the life of man, medical contributions were among the first to be published. Very early, however, medicine was merely included in publications dealing with science in general. Then as medicine began to specialize and as the value of medical publications for medical advancement began to be realized, periodicals multiplied tremendously.

In a lecture recently delivered by Prof. William Bulloch¹ he reminds us that John Shaw Billings estimated in 1881 that there were 180,000 doctors in the world and that 1,600 of them were contributors to medical literature. In the medical journals of 1879 available to him he counted 20,000 original articles. Today it is estimated that there are something like 400,000 doctors in the world, and the world list of scientific periodicals indicates 23,000 in all, of which 5,000 are medical. Of those periodicals listed as medical it is quite certain that the majority are mediocre and could be committed to oblivion without loss to the profession. Among these are house organs for proprietary products, bulletins recording local statistics, trade journals associated with the promotion of special institutions and similar publications.

In his survey of medical literature Professor Bulloch used as a basic work the *Index Catalogue* of the Surgeon General's Library. Up to 1893 he counted 7,000 articles and books on syphilis. Between 1893 and 1912 there were 14,000 new articles on the subject and from 1913 to 1932, 21,000 more. As an example of the way in which certain subjects receive medical attention, he notes in the course of twenty years 6,780 articles on heart disease and 1,280 on excision of the tonsils. Although vitamins were first interesting around 1914,

more than 1,000 articles on vitamins had been published by 1932. Between 1893 and 1932 there were published 34,000 articles on tuberculosis, or at the rate of two new articles on tuberculosis every day.

In his consideration of the indexing of such literature and its availability to the profession, Professor Bulloch paid special tribute to the *Index Catalogue* of the Surgeon General's Library, regarding it as the greatest publication of its kind ever achieved. He recorded also the history of the *Quarterly Cumulative Index Medicus* and said that an immense debt of gratitude was owing from the world of medicine to the American Medical Association for the publication of this work. Without the *Quarterly Cumulative Index Medicus* the vast amounts of medical periodical literature, now approximating a quarter of a million titles every six months, would be for the most part wasted. This is the literature made available to the medical profession through the *Quarterly Cumulative Index Medicus*. This index now provides a reference service to 1,200 medical publications, although only a few libraries in the entire American continent even approximate this number of publications. Indeed, the majority of medical libraries receive well under 200 medical periodicals. Nevertheless, by a system of lending, all the publications received in the Army Medical Library and in the headquarters of the American Medical Association are available to physicians. The *Quarterly Cumulative Index Medicus* represents a considerable financial burden to the Association. Professor Bulloch's commendation is a well merited recognition of this service to scientific medicine.

RADIANT ENERGY AND BONE HEALING

The important functions that have been assigned in experimental and clinical medicine to radiant energy of certain wavelengths have given tremendous impetus to researches in this field. The role of ultraviolet radiation in metabolism and the relationship between this type of radiation and vitamin D are observations that not only stimulate the scientific mind but appeal to the imagination of the public at large. Thus, unfortunately, has resulted in much commercialism and has set up a false conception of radiant energy as a panacea. Sunlight or artificial radiation is not a specific form of treatment and should not be used without medical guidance and adequate equipment. This form of therapy may play a prominent part in certain abnormal conditions, it is of minor importance in the life of normal persons who are provided with a completely adequate diet.

The proper use of radiation and irradiated materials has often caused remarkable results, among the more prominent of which are the effects on serum calcium and inorganic phosphorus in the healing of rickets and in osteomalacia. These results have led to the study of the use of radiant energy in the healing of fractures.

¹ Professor Bulloch's Schorstein Lecture. Brit. M. J. 2: 810 (Oct 26) 1935.

Two widely divergent views have developed. On the one hand there is the opinion, supported by clinical experience, that ultraviolet radiation is of some benefit in cases of ununited fractures¹. In contrast to this view is that which holds that ultraviolet radiation does not influence the union of fractures² and that the effect of radiation on serum calcium and phosphorus is of little significance in this respect. It would seem that there is no definite correlation between analytic variations of these two elements and the healing of the fracture³.

A detailed investigation of the effect of carbon arc radiation on the healing of bone has recently been reported by Sweeney and Laurens⁴. Experimental fractures of the fibula were studied in twenty-five normal dogs and eighty normal rats. In the majority of the experiments with the dogs, each animal served as its own control, that is, the fibula on one side was fractured, and then, after completely healing, the fibula on the other side was broken in as similar a manner as possible. During the healing of the second fracture the animal was irradiated. In some instances the procedure was varied by irradiating the animal while the first fractured fibula was healing and not irradiating after the second fracture was made. In still another group of dogs, carbon arc radiation was administered in the same amounts per unit of time during the healing of the two fractures. Finally, in a few experiments irradiation was not given during the healing period.

In the studies with the rat, the large number of animals available made it possible to use a group of from seven to ten animals as controls for two irradiated groups of a series. The fractures in all animals were identical and each rat had only one fracture and one period of healing. Measured amounts of carbon arc radiation were given during the healing periods, and roentgenograms were taken at intervals to show the progress of the repair process.

Determinations also of serum calcium and phosphorus were conducted on the dogs at frequent intervals. The results of these carefully conducted experiments indicate that during the stated periods of healing, and omitting consideration of certain abnormal healing rates in several dog experiments, the average repair time for all the fractures was 37 days shorter when the animals were irradiated than when they were not. It is striking that the acceleration of healing was obtained with one type of carbon lamp, irradiation also from another source was used but, in contrast to the former, it actually retarded the healing process. This result may be attributed to the different spectrums produced by the two types of lamps.

Although the extent of shortening of the healing period of the fractures may be too small to be of prime practical or economic significance, the results seem to contribute some helpful information to the controversy regarding the processes involved. The calcium and phosphorus determinations demonstrate that there is no apparent correlation between the concentrations of these elements and the rate of healing of a fracture and ossification. This would seem to suggest that the calcium-phosphorus product of the serum is of little significance as a prognostic index of the rate of bone regeneration. It is true that these experiments were conducted on presumably normal animals with normal bone-regenerating ability. Sweeney and Laurens point out the possibility that, with abnormal animals under the same experimental conditions, all other factors remaining constant, the results might have been a great deal different. This is particularly true in certain cases of fracture due to abnormal bone metabolism.

DUST STORMS AND HEALTH

The extraordinary conditions of drought in parts of Kansas, Colorado, New Mexico, Texas and Oklahoma, which gave rise to dust storms of unprecedented intensity and duration from February to May of this year, received wide interest and publicity. A study of the possible effect on health of these dust storms has recently been published¹. April 29 a "dust conference" was held at Liberal, Kan., the approximate center of the "dust bowl." State health officers from Oklahoma, Colorado and Kansas were present. At this time a comparison of morbidity and mortality for certain of the acute infectious diseases showed similar increases in the three states. Considerable interest was expressed in the bacterial and chemical content of the dust. Two of the Kansas sanitary and public health officials made trips into the dust area and exposed agar plates to secure an index of the number of micro-organisms present in the air during dust storms. The predominating bacteria observed were spore-forming soil types. Molds were almost as numerous as bacteria, and some yeasts were observed. Colon bacillus determinations were made. Characteristic organisms of this group, however, were obtained from only one sample of the nineteen tested.

The role of siliceous dusts in the production of silicosis is well known. The harmfulness of a given dust is dependent on three factors: the amount suspended in the air, the duration of exposure, and the particle size. It is now generally agreed that in the case of quartz-containing dusts the dangerous particles are usually between 0.5 and 5 microns in diameter and are almost always less than 10 microns. The six dust samples analyzed gave a silica content varying from

66.9 to 92.9 per cent. The size of the particles varied from 2 to 770 microns. The average values were much higher than those reported for the usual industrial and outdoor dusts.

Kansas experienced its most severe measles epidemic during the five months from January 1 to June 8, with 40,000 cases reported as compared with the previous high total of 22,464 for the twelve months of 1917. In addition to measles, acute respiratory infections prevailed throughout the state in unusually large numbers. Numerous cases also of streptococcal sore throat and corneal ulcers and eye infections were reported. There was no evidence, however, that any pathogenic organisms were carried by dust and therefore the direct cause of the increase in respiratory infections could not be attributed to this factor. The dust was exceedingly irritating to the mucous membranes of the respiratory tract, and this appeared to be a definite contributory factor in the development of many acute infections.

The action on health of dust storms may thus be divided into "immediate" and "future" effects. The former are manifest by the increase in morbidity and mortality from the acute infections of the respiratory tract probably due more to the irritating effect of the dust than to the carrying of pathogenic organisms. The future effect is unknown. It is possible that over a long period the effect might be similar to that seen in persons exposed to mine and other industrial dusts, though the difference in average size of the particles might prevent this from occurring. The most important conclusion is that the dust proofing of houses and the wearing of masks are essential to the comfort and welfare of persons living in areas affected by similar dust storms.

Current Comment

ABSORPTION FROM THE MIDDLE EAR

The fact that epithelial tissue other than that lining the lumen of the gastro-intestinal tract may be permeable to a large number of substances is well known. Vitamin D, for example, may be absorbed through the skin, and lead readily passes through pulmonary epithelium. Recently the possibility of the absorption of substances from the middle ear has been studied. In the normal subject this question would have little significance, as the middle ear, in addition to being small, is closed externally and is rather remotely open to the posterior part of the nasal cavity. In cases of infection of the middle ear, however, an absorption of toxic substances might well occur, as is indicated by the development of fever, leukocytosis and general malaise. Experimental data favoring this view have been obtained.¹ Solutions of drugs that exert easily recognizable effects, such as nicotine, which raises blood pressure, and sodium nitrite, which lowers blood pres-

sure, were injected through the ear drum into the middle ear of dogs. The position of the animal's head was adjusted so that none of the injected material could escape by way either of the eustachian tube or of the external canal. Nicotine produced a maximal rise in blood pressure within five minutes after injection, and in one instance within thirty-six seconds. The maximum decrease in blood pressure from sodium nitrite occurred in seven minutes and from histamine in three minutes. Similar evidence of rapid absorption was obtained with other drugs, including atropine, pilocarpine, strychnine, cocaine, procaine, ethyl alcohol, methyl alcohol, quinine, hydrochloric acid, hypertonic sodium chloride, and sodium hydroxide. These observations leave little reason to doubt that the absorption of a variety of substances from the middle ear may occur.

PIGMENTS OF HUMAN FAT

The fat of many mammals, including man, contains a colored material the nature of which is not clearly understood. An interesting contribution to this problem has been made recently by two Hungarian investigators.¹ Human fat, usually obtained from the abdominal wall or mesenteries, was taken at necropsy from patients who had died of various diseases. The fat was saponified and the remaining pigment was fractionated into its components by means of organic solvents and adsorption in a column of calcium hydroxide. Four distinct pigments were obtained, which were subsequently identified by means of the spectroscope as carotene, lycopene, xanthophyll and capsanthine. Carotene and lycopene were isolated also in crystalline form. Each of these four pigments is known to be widely distributed in the plant kingdom. Some information concerning the actual amounts of the pigments present in the original fat was secured by comparing their solutions with known colored solutions in a microcolorimeter. In the majority of cases the values for total pigment varied between 1 and 3.5 mg. per kilogram of fat, carotene and xanthophyll were present in larger amounts than were lycopene and capsanthine. In a case of cancer of the uterus and in one of icterus, excessively high lipochrome values, 64 and 155 mg. per kilogram respectively, were found. The increase appeared to be a result of an equal elevation in the concentration of each of the four pigments. The significance of these unique observations is as yet largely a matter of conjecture. Apparently the nature of the disease processes in the subject is of some importance. Undoubtedly the chief source of the pigments was the vegetable constituents of the diet. Indeed, it was observed that the fat from subjects who had ingested considerable amounts of red pepper with their food was usually quite rich in capsanthine, one of the pigments of the pepper plant. Furthermore, it is well known that man cannot synthesize carotene, the pro-vitamin A, but depends ultimately on plants for his supply.

THE KANSAS CITY SESSION

Appointments of Section Representatives to Scientific Exhibit

Representatives from the various sections of the Scientific Assembly have been appointed to the Scientific Exhibit for the Kansas City session as follows

- PRACTICE OF MEDICINE**
Irving S Wright, New York
- SURGERY, GENERAL AND ABDOMINAL**
R S Dinsmore Jr, Cleveland
- OBSTETRICS, GYNECOLOGY AND ABDOMINAL SURGERY**
H Close Hesselstine, Chicago
- OPHTHALMOLOGY**
Georgiana Dvorak-Theobald, Oak Park, Ill
- LARYNGOLOGY, OTOTOLOGY AND RHINOLOGY**
John L Myers, Kansas City, Mo
- PEDIATRICS**
F Thomas Mitchell, Memphis, Tenn
- PHARMACOLOGY AND THERAPEUTICS**
Ralph H Major, Kansas City, Mo
- PATHOLOGY AND PHYSIOLOGY**
J P Simonds, Chicago
- NERVOUS AND MENTAL DISEASES**
Peter Bassoe, Chicago
- DERMATOLOGY AND SYPHILOLOGY**
Clark W Finnerud, Chicago
- PREVENTIVE AND INDUSTRIAL MEDICINE AND PUBLIC HEALTH**
Paul A Davis, Akron, Ohio
- UROLOGY**
Russell S Ferguson, New York
- ORTHOPEDIC SURGERY**
R L Diveley, Kansas City Mo
- GASTRO-ENTEROLOGY AND PROCTOLOGY**
J A Bargen, Rochester, Minn
- RADIOLOGY**
S W Donaldson, Ann Arbor, Mich

RADIO BROADCASTS

The American Medical Association broadcasts over the Blue network and certain additional stations of the National Broadcasting Company at 5 p m eastern standard time (4 o'clock central standard time, 3 o'clock mountain time, 2 o'clock Pacific time) each Tuesday, presenting a dramatized program with incidental music under the general theme of Medical Emergencies and How They Are Met. The title of the program is 'Your Health'. The program is recognizable by a musical salutation through which the voice of the announcer offers a toast 'Ladies and gentlemen your health!'. The theme of the program is repeated each week in the opening announcement, which informs the listener that the same medical knowledge and the same doctors that are mobilized for the meeting of grave medical emergencies are available in every community, day and night, for the promotion of the health of the people. Each program will include a brief talk dealing with the central theme of the individual broadcast.

The next three programs are as follows

- November 26 Common Household Emergencies W W Bauer, M D
December 3 Tuberculosis Morris Fishbein M D
December 10 Hunting Accidents Morris Fishbein M D

This program is broadcast also on the short waves through KDKA, Pittsburgh, over station W8AK, 11,870 and 12,210 kilocycles

ARKANSAS

New Medical Building for State University—The new building of the University of Arkansas School of Medicine was opened for classes October 1. Built with a loan and grant of \$500,000 from the Public Works Administration, the new structure accommodating 300 students, is five stories high with a sixth story, suggesting a penthouse, in the center. It is of modern American architecture with an exterior of buff-colored face brick and limestone trim. The main entrance is of Batesville limestone. Each department has been allotted space on the first floor. The second floor is occupied by the dean's office, general offices, library, cafeteria and lecture room. The pathology and bacteriology departments occupy the third floor with laboratories for each, museum for pathologic specimens, laboratory for student technicians and an assembly room. The fourth floor is divided between the physiology and chemistry departments. The fifth floor is given over to the departments of anatomy and histology. The sixth floor provides space for a small laboratory for distillation of water, an incubator, a small research laboratory, and cages for animals used in teaching and research. A door opens from the penthouse to the roof where there are larger dog cages, with concrete houses to

University of Arkansas Medical Building

protect the animals from the elements, and three pools for frogs and terrapins used by physiology classes. The Folsom Clinic, formerly in a building adjoining the old medical structure, occupies the first floor and half of the second. Dr Frank Vinsonhaler has been dean of the school of medicine since 1927 and associated with it since 1893. Although designated a department of the old Arkansas Industrial University, the medical school was not actually affiliated with it and was operated by its physician sponsors for thirty-two years as a private institution. In 1911 the legislature accepted an offer of the faculty of the school to transfer the property to the state, provided it would be maintained as a part of the University of Arkansas. Since 1912 it has been operated in the old statehouse, where it was moved at that time.

CALIFORNIA

Psittacosis Reported—Psittacosis was believed the cause of one death and two cases of illness in San Francisco recently, newspapers reported October 24. What was thought to be a new case of the disease was on that day under observation in the San Francisco Hospital.

Changes in Faculty at Stanford—Dr Arthur A O'Neill, a member of the faculty of Stanford University School of Medicine since 1913, has been made assistant clinical professor of medicine, emeritus according to a recent announcement from the dean, Dr Loren R. Chandler. James P. Baumberger, D.Sc., has been promoted from associate professor to professor of physiology and Dr Maurice L. Tamter from associate professor to professor of pharmacology. Other promotions include those of Charles E. Clifton, Ph.D., from assistant professor to associate professor of bacteriology, John Field II, Ph.D., from assistant professor to associate professor of physiology, Drs Victor E. Hall from assistant professor to associate professor of physiology, and John K. Lewis from assistant professor to associate professor of medicine.

Memorial Plaque Unveiled—A bronze plaque was unveiled at the library of the Los Angeles County Medical Association, November 7, in honor of the late Dr Theodore C Lyster, Los Angeles. Dr George Dock, Pasadena, chairman of the library committee, presided. Dr Lyster graduated from the University of Michigan Medical School, Ann Arbor, in 1899. He entered the U S Army in 1900 and was advanced through the various grades until 1930, when he was retired with the rank of brigadier general. He was chief of aviation and professional services in the surgeon general's office, Washington, D C, in 1917-1918, for which he received the Distinguished Service Medal. For four years he was a director of yellow fever elimination for the Rockefeller Foundation. In 1913, during the American occupation, he was chief health officer of Vera Cruz, Mexico. He was a past president of the Southern California Medical Association and at the time of his death in 1933 was associate clinical professor of ophthalmology, University of Southern California School of Medicine, Los Angeles. Dr Lyster was interested in the Barlow Library, serving first as trustee and later as president.

DELAWARE

State Medical Election.—Dr Joseph B Waples Jr, Georgetown, was chosen president of the Medical Society of Delaware at the recent annual meeting in Wilmington, he will take office January 1. Dr William H Speer, Wilmington, was reelected secretary. The society will hold its next annual meeting in Rehoboth, October 12-14.

DISTRICT OF COLUMBIA

Personal—Dr Hugh S Cumming surgeon general, U S Public Health Service, has been appointed one of an executive committee of ten, named by the Health Section of the League of Nations at its recent meeting in Geneva. Dr Cumming was one of the few delegates representing nations outside the league who were appointed to the special group.

Remington Medal to Dr Hilton—Samuel Louis Hilton, Pharm D, Washington, was presented with the Remington Medal by the New York branch of the American Pharmaceutical Association, October 19. The presentation was made at a dinner given to Dr Hilton by the New York branch, the District of Columbia Pharmaceutical Association, the District of Columbia Veteran Druggists' Association, the faculty of the school of pharmacy of George Washington University and the District of Columbia Board of Pharmacy. The medal is awarded annually to the man or woman who has done most for American pharmacy during the preceding year. Dr Hilton, who has served on the U S Pharmacopeia Revision Committee, has been secretary of the district board of pharmacy for eight years.

ILLINOIS

Society News—Dr Lee C Gatewood, Chicago, discussed the diagnosis and treatment of colitis before the Peoria City Medical Society, November 5.—Dr M Herbert Barker, Chicago, addressed the La Salle County Medical Society, October 30, on nephritis, and Dr George E. Shambaugh Jr, "What Can Be Done for Sinus Disease".—Dr Abraham F Lash, Chicago, discussed "Puerperal Sepsis" before the Will-Grundy County Medical Society in Joliet, October 30.—Dr Karl A Meyer, Chicago, discussed "Regional Enteritis Symptoms, Diagnosis and Treatment" before the Adams County Medical Society in Quincy, November 11.—Dr John Albert Key, St Louis, discussed fractures of the joints before the Madison County Medical Society at a meeting in Alton, November 1.

Chicago

Course in Mental Hygiene—The management of children's behavior problems is the theme of a course that opened at the University of Illinois College of Medicine November 18, to continue for eight weeks. The meetings will be held at the Institute for Juvenile Research and the fee is \$10. The course is of particular interest to pediatricians, but other interested physicians are invited.

Dr Hastings Goes to Harvard—A Baird Hastings, Ph D, has resigned as professor of biochemistry in the department of medicine, University of Chicago, to accept the Hamilton Kuhn professorship in biologic chemistry at Harvard Medical School, Boston, succeeding the late Otto Folin. Dr Hastings studied at the University of Michigan and Columbia University receiving the degree of doctor of philosophy from the latter school. He served as a chemist with the U S Public Health Service from 1917 to 1921 as an assistant at the Rockefeller Institute for Medical Research from 1921 to 1922 and associate from 1922 to 1926, when he became

professor of physiologic chemistry at the University of Chicago. Since 1928 he has been professor of biochemistry in the department of medicine. Dr Hastings was visiting professor to Peiping Union Medical College in 1931.

Retiring Professors Honored.—Three professors retiring from the faculty of Loyola University School of Medicine were honored at a dinner at the Palmer House, November 14. Dr Ulysses J Grim is retiring as head of the department of otolaryngology, Dr George W Mahoney of the department of ophthalmology, and Dr Frank M Phifer, the department of genito-urinary diseases. Dr Grim who has been associated with Loyola since 1910, will be succeeded by Dr George T Jordan, clinical professor of ear, nose and throat diseases. Dr Carl F Schaub, clinical instructor in ophthalmology, will succeed Dr Mahoney, who has been connected with the school since 1918. Dr Phifer's successor will be Dr Herbert E Landes, clinical professor of urology. Dr Phifer was appointed professor in 1919 and has been head of the department since 1927. The new appointees will serve until permanent heads are chosen, it was stated. Reuben M Strong, Ph D, secretary of the medical school faculty, was toastmaster at the dinner and Dr Louis D Moorhead, dean of the school, gave the principal address.

Society News—A clinical dermatology program was presented before the Chicago Medical Society, November 6, representing the medical school of the University of Illinois were Drs Theodore Cornbleet and Herbert Rattner. Loyola University, Benjamin Barker Beeson and Vincent B Bowler. Northwestern University, Arthur W Stillians and Erwin P Zeisler, and Rush Medical College, Edward A Oliver and Michael H Ebert. Speakers before the society November 13 were Drs James S Mc Lester Birmingham, President, and James Tate Mason, Seattle. President-Elect of the American Medical Association, on "Clinical Aspects of Nutritional Failure in America" and "Some Considerations in the Etiology and the Surgical Treatment of Peptic Ulcers," respectively.

INDIANA

Debate on Socialized Medicine—Dr Morris Fishbein, Chicago, editor of THE JOURNAL and William Trufant Foster, director of the Pollak Foundation, will discuss the negative and affirmative aspects respectively, of socialized medicine, December 7, when the Indiana High School Debating League will hold a conference at Purdue University, Lafayette.

Society News—A symposium on poliomyelitis was presented before the Lawrence County Medical Society, November 6 by Drs Virgil E Simpson William H Allen, James H Pritchett and Richard T Hudson, all of Louisville, Ky.—Dr Harlan A English, Danville, discussed "Diagnosis and Treatment of Disorders of the Prostate" before the Fountain Warren County Medical Society in Covington November 7.—At a meeting of the Huntington County Medical Society, October 5, Dr Murray N Hadley Indianapolis, spoke on "Appendicitis in Children".—Dr Bernard Fantus, Chicago, discussed "Therapy of Cough" before the Allen County Medical Society in Fort Wayne, November 5.—Dr Arthur N Ferguson addressed the Fort Wayne Academy of Medicine, October 22, on "Mechanics of Referred Pain."

KANSAS

Society News—Drs Charles C Conover and Everett R Deweese Kansas City, discussed "Chronic Functional Disorders of the Colon" before the Kansas-Nebraska Medical Association, October 17 in Hiawatha.—Speakers before the Butler-Greenwood County Medical Society in Eureka, October 18, included Dr Howard E Marchbanks, Pittsburg, on "Hypertensive Heart Disease".—The Northwest Kansas Medical Society was addressed in Norton, October 23, by Drs Leroy A Calkins, Kansas City, Mo and Charles F Taylor, Norton, on "Carcinoma of the Cervix" and "Surgery in Pulmonary Tuberculosis," respectively.

LOUISIANA

Society News—At a meeting of the Orleans Parish Medical Society, November 11, Drs Gladys Richarda Williamson and Robert A Strong, New Orleans, discussed "Erythroblastic Anemia." Idys M Gage, "Pilonidal Sinus," and Charles B. Odum, "A Review of Page's Epidural Anesthesia with a Report of 100 Cases".—At a meeting of the Sixth District Medical Society, October 24 in Jackson, speakers were Drs Gilbert C Anderson, New Orleans, "Signs and Symptoms of Brain Diseases," and Irvine Ashton Rohms, Baton Rouge, "Coronary Thrombosis."

MINNESOTA

Special Scientific Session—The Ramsey County Medical Society arranged a special scientific session in St. Paul, November 22-23 Friday evening, Drs Arnold Schwyzer and Joseph Borg, both of St Paul, discussed pain in the right side of the abdomen, while Saturday morning was given over to a clinical pathologic conference under the leadership of Dr John F Noble Wisconsin physicians attending the Wisconsin-Minnesota football game were invited

Veterinarian Honored—At the annual dinner of the Minnesota Public Health Association in Minneapolis, November 22, Charles E Cotton, D.V.M., secretary and executive officer of the Minnesota Livestock Sanitary Board, was the guest of honor, in recognition of his work in the eradication of bovine tuberculosis Speakers at the dinner included Drs Morris Fishbein, Chicago, editor of *THE JOURNAL*, Charles H Mayo, Rochester, president of the state public health association, J Arthur Myers, professor of medicine and preventive medicine and public health, University of Minnesota School of Medicine and Mr Frederick E Murphy, publisher of the Minneapolis *Tribune* Dr Oscar E Locken, Crookston was toastmaster

Dr Pottenger Gives Bell Lecture—Dr Francis M Pottenger, Los Angeles, will deliver the John W Bell Memorial Lecture of the Hennepin County Medical Society Minneapolis, December 2, on "Diagnosis of Tuberculosis" This lectureship was established in 1934 by the Hennepin County Tuberculosis Society, in honor of the late Dr Bell The lecture is to be delivered at the December meeting each year of the county medical society Dr Bell, who died in 1933, was a member of the House of Delegates of the American Medical Association from 1919 to 1923 He also served as president of the Minnesota State Medical Association, Hennepin County Medical Society and the Minnesota Academy of Medicine, and was a member of the state senate from 1891 to 1895 (*THE JOURNAL*, Aug 18, 1934, p 496)

MISSISSIPPI

Society News—Dr Richard D Sessions, Natchez discussed "Pancreatic Cysts and Pancreatic Abscess" before the Adams County Medical Society in Natchez, recently—Speakers before the Delta Medical Society in Moorhead, October 9, included Drs Carl R Crutchfield, Nashville, Tenn, on "Treatment of Fibroid Tumors" and William S Taylor Isola, "Comatose Malaria"—Dr John H Musser, New Orleans, addressed the Pike County Medical Society, October 5, on "Cholecystitis and Cholelithiasis"—Speakers before the Central Medical Society, Jackson, October 1, included Dr Harvey F Garrison Sr Jackson, on "Purpura Haemorrhagica"—At a meeting of the Homochitto Valley Medical Society in Natchez October 10, papers were presented by Drs Jacob S Ullman and Homer A Whittington on "Menstruation and the Hormones" and "Essential Hypertension," respectively—The Issaquena-Sharkey-Warren Counties Medical Society was addressed in Vicksburg, November 12, by Drs Raymond H Potts New Orleans Laurance J Clark and William K Purks Vicksburg they presented a symposium on rheumatic heart disease—Speakers before the North Mississippi Medical Society in Oxford, October 18 included Dr Otis S Warr, Memphis, Tenn., on "Management of the Patient with Heart Failure."

MISSOURI

Conference on Social Hygiene—The Missouri Social Hygiene Association, cooperating with the St Louis Medical Society, held a conference, October 24, to afford employers and physicians opportunity to discuss social hygiene in its relation to industry Dr Richard S Weiss assistant professor of clinical dermatology Washington University School of Medicine, talked on "Venereal Disease as a Problem for Industry", Dr Ben F May "Venereal Disease and the Community", and Dr Paul J Zentay, president of the social hygiene association "What Can Be Done About It?"

Red Cross Medal to Mrs Elsbeth Vaughan—The International Committee of the Red Cross Geneva, Switzerland, awarded the Nightingale Medal to Mrs Elsbeth Vaughan, St. Louis recently, the presentation will probably take place at the annual meeting of the board of incorporators it was stated Mrs Vaughan is the widow of the late Dr Victor C Vaughan, Detroit. She has been associated with the American Red Cross since early in 1917 in this country and abroad and since 1924 as assistant director of Red Cross Nursing of the midwest branch office in St Louis During the World War she assisted with the organization of nurses for military service. In her present position, Mrs Vaughan directs Red Cross nursing activities in seventeen states included in the area allocated to the midwest branch, according to Milwaukee *Medical Times*

NEBRASKA

Society News—The Seventh Councilor District Medical Society held its annual meeting in Harvard, October 17 with the following speakers among others Drs John R Nilsson, Omaha Operative Technic and After-Treatment, with End Results, in the Treatment of Severe Esophageal Stricture" Robert D Schrock, Omaha, "Fractures of the Tibia into the Knee Joint" and John F Allen Omaha, "Treatment of Mammal or Early Pulmonary Tuberculosis"—Dr Leroy A Calkins Kansas City Mo addressed the Omaha-Douglas County Medical Society October 9, on "Management of the Occipitoposterior Presentation" The society devoted its meeting of October 22 to dedication of the Omaha-Douglas County Central Health Service—The Northwest Nebraska Medical Society, including the counties of Dawes Sioux and Sheridan was organized at Chadron, October 15—Drs John Marshall Neely and Clarence K Elliott, Lincoln, addressed the Lancaster County Medical Society, October 1, on "The Value of Biopsy and Relation of Salts of Blood to Edema," respectively

NEW YORK

Personal—Dr Charles E. Martin has been appointed medical director of Albany Hospital, Albany He has been a member of the staff for several years—Dr John N Hayes, Saranac Lake, has been appointed medical director of Sanatorium Gabriels, Gabriels

Society News—Drs Rosco G Leland Chicago director of the Bureau of Medical Economics, American Medical Association and Frederic E Elliott Brooklyn addressed the Medical Society of the County of Westchester, at White Plains November 19, on medical economics in the nation and in the state, respectively—Dr Edward K. Cravener, Schenectady, addressed the Medical Society of Montgomery County at Amsterdam October 30, on "Bone Atrophy Following Trivial Injuries and Its Compensation Angles" Dr Harold Jackson Davis Albany director of medical care for the Temporary Emergency Relief Administration and consultant on medical care for the Works Progress Administration, spoke on aspects of these projects of interest to the practicing physician

New York City

Hoerber Firm Affiliated with Harpers—The medical publishing firm of Paul B Hoerber, Inc., announces that it is now the Medical Book Department of Harper and Brothers, with offices at 49 East Thirty-Third Street.

Personal—Dr John N Evans, Brooklyn, has been appointed professor of clinical ophthalmology at Long Island College of Medicine Brooklyn—A portrait of Dr John M Wheeler, head of the Institute of Ophthalmology, Columbia University—Presbyterian Hospital Medical Center, was recently hung in the institute as a tribute to Dr Wheeler from his colleagues of the staff—Dr Edward Cathcart has resigned as associate dean of Columbia University College of Physicians and Surgeons to resume private practice in Detroit

Society News—A joint meeting of the Philadelphia Orthopedic Club and the section of orthopedic surgery of the New York Academy of Medicine was held at the academy, November 15 subjects discussed were scoliosis, equalization of the length of legs and recent developments in orthopedics Among speakers were Drs Kristian G Hansson Armitage Whitman, Philip D Wilson, Charles Murray Gratz and George Anopol A symposium on diabetes and pregnancy will be presented before the section of obstetrics and gynecology, November 26 by Drs Elliott P Joslin Raymond S Titus Priscilla White and George V Smith and Mrs O Watkins Smith, all of Boston.—Dr Geza Nemet addressed the New York Roentgen Society, November 18, on "Roentgen Diagnosis of the Heart and Great Vessels"—Drs Boris A Kornblith and Seaton Sailer will address the New York Pathological Society, November 26 on "Lymphogranuloma Venereum" and "Primary Sarcoma of the Breast" respectively—Dr Julius Lewis Amster addressed the American Society for Regional Anesthesia at the New York Academy of Medicine in October on "Spinal Anesthesia for Poor Pediatric Surgical Risks"

Death of Dr Osborn—Henry Fairfield Osborn, Sc.D, for many years president of the American Museum of Natural History, died suddenly November 6 of a heart attack at his home in Garrison, aged 78 Dr Osborn was graduated from Princeton University and taught natural science there for several years In 1890 he joined the faculty of Columbia University as professor of biology and from 1910 until his death was research professor of zoology His connection with the American Museum began in 1891, when he was appointed curator of the department of vertebrate paleontology he was made president in 1908 Among many other activities

Dr Osborn served as vertebrate paleontologist to the U S Geological Survey from 1900 to 1924 and since that time had borne the title of senior geologist. He had served as president of many scientific organizations, among them the second International Congress of Eugenics and American Association for the Advancement of Science. In addition he was a member of numerous foreign societies and had received honorary degrees from universities both in the United States and abroad. In 1923 he received the gold medal of the Roosevelt Memorial Association and at various times was honored with other awards. He retired from the presidency of the museum in 1933 with the title of honorary president.

NORTH DAKOTA

New Members of State Board—Drs John E. Countryman, Grafton, Harry A. Brandes, Bismarck, and William H. Long, Fargo, were recently appointed members of the North Dakota State Board of Medical Examiners. Present officers of the board are Drs William C. Fawcett, Starkweather, president, and George M. Williamson, Grand Forks, secretary-treasurer and general administrative officer.

OHIO

Dr Houssay to Deliver Hanna Lecture—Dr Bernardo Alberto Houssay, professor of physiology, National University of Buenos Aires, Argentina, will deliver the thirty-sixth Hanna Lecture, December 3, at the Cleveland Institute of Pathology, on "The Hypophysis and Carbohydrate Metabolism."

Eugenics Research Prize—Dr Serge Androp of the staff of the Ohio Hospital for Epileptics, Gallipolis, has been awarded a prize of \$3,000 offered by the Eugenics Research Association for original research on the probability of commitment for a mental disorder of any kind, based on the individual's family history. The contest was announced in 1933.

Society News—Dr Virgil S. Counsellor, Rochester, Minn., addressed the Highland County Medical Society, Hillsboro, October 11, on diseases of the pelvis. Drs William W. Trostel, Piqua, and Emory R. Irvin, Bradford, addressed the Miami County Medical Society, Piqua, October 11, on obstetric care. Dr Howard T. Karsner, Cleveland, was guest speaker at a meeting of the Lorain County Medical Society, Lorain, October 9, on "Pathology of Bright's Disease." Drs Floyd C. Hendrickson, Canton, and George N. Wenger, Massillon, addressed the Stark County Medical Society, Canton, October 7, on "Vesical Neck Obstruction in the Female" and "Lumbar and Sacral Anesthesia in Perineal Surgery," respectively. At a meeting of the Columbus Academy of Medicine, October 21, Dr Donald E. Yochem, Newark, spoke on "Intercostal Nerve Blocking in the Treatment of Pulmonary Diseases." Dr John H. Warvel, Indianapolis, discussed "The Management of Diabetes" before the Montgomery County Medical Society in Dayton, November 15. Dr Ralph W. Good, Cincinnati, will address the society, December 6, on "Indications for Splenectomy." Dr Henry L. Bockus, Philadelphia, was guest speaker at a meeting of the Union Medical Association (Sixth Council District) in Youngstown, November 19, on "The Role of Infection and of Disturbed Cholesterol Metabolism in the Genesis of Gallstones."

PENNSYLVANIA

Society News—Dr Sumner L. S. Koch, Chicago, addressed the Erie County Medical Society, Erie, November 6, on surgery of tendons and nerves and skin grafting. Dr Curtis C. Mechling, Pittsburgh, addressed the Cambria County Medical Society, Johnstown, November 14, on "Diagnosis and Office Treatment of Anorectal Disorders."

Philadelphia

Reunion of Resident Physicians—The forty-ninth annual dinner of the Association of Ex-Resident and Resident Physicians of the Philadelphia General Hospital will be held at the Art Club, Philadelphia, December 3. The guest of honor will be Dr Benjamin Franklin Stahl. Clinics will be given in the afternoon at the hospital by Drs George E. Pfahler, Edward J. G. Beardsley, Daniel J. McCarthy, Kenneth M. Lynch, Philip Williams and David Riesman. Ex-interns are asked to send their correct addresses to Dr George Wilson, 133 South Thirty-Sixth Street, Philadelphia.

SOUTH DAKOTA

Personal—Dr Gregory R. Waters, formerly of Chicago, was recently appointed resident physician for the Yankton Sioux Indians at Greenwood, S. D.—Dr Edwin L. Perkins, Sioux Falls, has been appointed physician to the South Dakota penitentiary, succeeding the late Dr William T. Keller.

TEXAS

District Meetings—At the semiannual meeting of the Panhandle District Medical Society at Plainview, October 15-16, guest speakers included Drs George D. Huff, San Diego, on "The Technic of Episiotomy," Nelson M. Percy, Chicago, "Surgery of the Superior Hypogastric Plexus of the Sympathetic Nervous System," Carroll M. Pounders, Oklahoma City, "Treatment of Pneumonia in Infants and Children," and Ray M. Balyeat, Oklahoma City, "Iodized Oil in Treatment of Intractable Asthma." Speakers at a meeting of the Eleventh District Medical Society in Rush, October 15, included Drs George D. Mahon Jr., Dallas, on "Complications of Thyroid Surgery," Joseph B. Foster, Houston, "Treatment of Fractures of the Lower Extremity," and Edward White, Dallas, "Urinary Calculi." At the thirtieth annual meeting of the Fourth District Medical Society in Brady, October 23-24, speakers included Drs Earl B. Ritchie, San Antonio, on "Ringworm Infection of the Skin," Eugene V. Powell, Temple, "Results of Roentgen Therapy of Carbuncles and Other Infectious Reactions," Dewey Sutton, San Angelo, "Mesenteric Vascular Occlusion," and James Shirley Sweeney, Dallas, "Juvenile and Adult Diabetes."

WASHINGTON

Health at Spokane—Telegraphic reports to the U. S. Department of Commerce from eighty-six cities with a population of 37 million, for the week ended November 9, indicate that the highest mortality rate (20.4) appears for Spokane, the rate for the group of cities as a whole was 10.8. The mortality rate for Spokane for the corresponding week of 1934 was 14.6 and for the group of cities, 11.1. The annual rate for the eighty-six cities was 11.3 for the forty-five weeks of 1935 and the same rate appeared for the corresponding period of last year. Caution should be used in interpretation of these weekly figures, as they fluctuate widely. The fact that a city is a hospital center for a large area or that it has a large Negro population may tend to increase the death rate.

WEST VIRGINIA

Professor Appointed—Dr Simon B. Chandler, associate professor of anatomy at Loyola University School of Medicine, Chicago, has been appointed professor and head of the department of anatomy at the University of West Virginia School of Medicine. Dr Chandler, who graduated in medicine at Northwestern University School of Medicine, Chicago, in 1927, taught anatomy at the University of Arkansas School of Medicine 1922-1924, and became associated with Loyola as assistant professor in 1926.

WISCONSIN

Fund for Research—A fund of \$7,800 has been donated to the University of Wisconsin School of Medicine, Madison, by E. R. Squibb and Sons Company, New York, for research on cyclopropane. The work will be under the direction of Dr Ralph M. Waters, professor of anesthesia.

Appointments at Marquette University—New appointments to the faculty of Marquette University School of Medicine, Milwaukee, for the current year include Drs John E. Mulsow, assistant clinical professor of laryngology, otology and rhinology, Armand J. Quick, assistant professor of pharmacology, Forrester Raine and Eugene A. Smith, assistant clinical professors of surgery. Mr Theodore Wiprud, executive secretary of the Medical Society of Milwaukee County, has been appointed lecturer in medical economics.

Society News—Drs Eben J. Carey and Francis D. Murphy, Milwaukee, were speakers at the annual meeting of the first councilor district of the State Medical Society of Wisconsin in Watertown, October 24, on "Anatomy and Physiology of the Heart" and "Diagnosis and Management of Heart Disease," respectively. Dr Carey also delivered an address at an evening banquet on "Social and Economic Aspects of Medical Education Today." Dr Robert E. Burns, Madison, addressed the Rock County Medical Society, Janesville, October 29, on "Orthopedic Cases of Interest to the General Practitioner." Guest speakers at the annual meeting of the tenth councilor district in Eau Claire in October were Drs Henry E. Michel, son, Minneapolis, on diseases of the skin, Francis D. Murphy, and Milwaukee, diagnosis and treatment of acute nephritis, and Harry B. Zimmermann, St. Paul, tumors of the breast. Dr Rock Sleyter, Wauwatosa, addressed the Waupaca County Medical Society in New London recently on "The Patient with Chronic Complaints." Drs Louis M. Warfield, Milwaukee, and Chester M. Kurtz, Madison, addressed the Medical Society of Milwaukee County, Milwaukee, November 8, on "Treatment of Heart Failure" and "Treatment of Peripheral

Circulatory Failure," respectively. Dr William C MacCarty, Rochester, Minn., gave the opening lecture in the society's current graduate course in gastro-enterology, November 4. Other lecturers in the series are Drs Ralph C Brown, Chicago, Lewis G Cole, New York, and Frank H Lahey, Boston.

PUERTO RICO

Annual Medical Meeting—The Puerto Rico Medical Association will hold its annual meeting at the association's building in Santurce, December 13-15. Dr Esteban Garcia Cabrera, San Juan, is president of the association and Dr Euripides Silva, San Juan, secretary. Members of the American Medical Association are invited to attend.

GENERAL

Society News—Dr Titus H Harris, Galveston, was chosen president of the Central Neuropsychiatric Association at its fourteenth annual meeting in Topeka, Kan., October 25-26. Other officers elected are Drs Benjamin Landis Elliott, Kansas City, Mo., vice president, and Henry W F Woltman, Rochester, Minn., secretary.

New Pharmacopeia Ready in December—The Eleventh Revision of the U S Pharmacopeia will be available December 16, according to an announcement by the board of trustees of the U S Pharmacopoeial Convention. Standards in the new revision will become effective June 1, 1936, superseding the tenth revision. Fifty-eight new substances have been added in the new revision.

Warning Against Impostor—Dr Eugene C Hood, medical superintendent of the Florence-Darlington Tuberculosis Sanatorium, Florence, S C., reports that a woman giving the name of Karr and her address as Cleveland recently cashed checks in Florence stores using the sanatorium falsely as a reference. In each case she told the merchants that she had been to the sanatorium to sell dairy equipment or that the institution "was a prospect for dairy equipment." As the sanatorium has no dairy, Dr Hood said, it has no need for dairy equipment. It is believed that the woman may impose on other hospitals in the same manner.

Change in Status of Licensure—The New York State Board of Medical Examiners reports the following action:

Dr Samuel Taylor Barton, Canastota, license suspended for one year March 15 on the basis of his having committed an abortion.

The California State Board of Medical Examiners reports the following action taken at a meeting in Sacramento, October 22:

Dr Fred M Bantum, Los Angeles, found guilty and placed on probation for five years during which time he shall not have or apply for a federal narcotic permit or have narcotics in his possession and he shall report at each annual Los Angeles meeting.

Dr Leonard R Chapman, Los Angeles, license revoked, found guilty of aiding and abetting an unlicensed practitioner.

Dr Averell H Owen, license restored and placed on probation for five years with the requirement that he report at each annual Los Angeles meeting.

Dr Eugene L Settles, formerly of San Diego, license restored and placed on five years probation without narcotic privileges.

Dr Arthur M Tweedie, Los Angeles, found guilty and placed on probation for five years during which time he shall not have or apply for a federal narcotic permit or have narcotics in his possession and ordered to report at each annual Los Angeles meeting.

The Michigan State Board of Registration in Medicine reports the following action taken at a meeting in Lansing, October 9:

Dr Alice G Vinton, formerly of Grand Rapids, license revoked on conviction of abortion.

The Texas State Board of Medical Examiners has recently reported the following action taken at the June meeting:

Licenses of Drs William Everett Wright, San Antonio, Lem Faulk Sulphur Springs, and T K Jones, Henrietta, revoked because of narcotic addiction.

License of Dr Joseph Clifford Jones, Spearman, revoked through district court because of fraud in obtaining it.

Four Companies Agree to Abandon Unfair Advertising—Four companies dealing in medicinal preparations have entered into stipulations with the Federal Trade Commission to abandon certain unfair advertising practices. These companies are the Koskott Company, New York; Carleton & Hovey Company, Lowell, Mass.; Smith Brothers Inc, Poughkeepsie, N Y, and Dr Louis L Sherman of Oakland, Calif., operating as Clinic of the Air. The commission reports that the Koskott Company, which sells preparations for treatment of the hair and scalp and for coloring the hair, agrees to stop representing that any of its preparations is an effective treatment for thinning or falling hair or that their use will prevent hair from falling or being brushed or combed from the head unless the advertising assertion is limited in reference to excessive thinning and excessive falling of the hair. Other similar representations will be discontinued.

The Carleton & Hovey Company, distributors of "Father John's Medicine," agrees to stop representing it as an effective therapeutic remedy for colds, coughs or throat troubles, it being understood that this agreement will not prevent the respondent from advertising the preparation as a treatment for colds, coughs due to colds or minor throat troubles. Father John's Medicine also will not be represented as effective in the treatment of colds, except by providing the beneficial effects of vitamin A. Other representations will be discontinued.

Smith Brothers, Inc, selling Smith Brothers' Cough Syrup and Smith Brothers' Cough Drops, stipulates that it will cease advertising the drops or the cough syrup as effective remedies for the treatment of colds or that either preparation has a unique advantage over other remedies due to vitamin A content.

Dr Louis L. Sherman, operating as "Clinic of the Air" and dealing in a list of preparations including "Liquid Ferrolax," "Calwhey" and "Red Label Enterol," agrees to cease advertising that these preparations or any combination of them constitute a competent treatment or effective remedy for any of a list of twenty-eight diseases ranging from acidosis, anemia and biliousness to rheumatism, spastic colon and tuberculosis. The respondent agrees also not to represent "Calwhey" as raising resistance or as assisting in eliminating poisons through the kidneys and to cease asserting that by hundreds of tests Calwhey is known to be effective in changing the intestinal flora. Numerous other representations of these preparations will be discontinued according to the stipulation.

Government Services

Thirty-One States Free from Bovine Tuberculosis

Massachusetts, South Carolina, Georgia, Alabama and Louisiana have recently been designated as modified accredited areas by the U S Department of Agriculture, signifying that they are practically free from tuberculosis of cattle. Federal funds were used in the testing that achieved this result. Thirty-one states are now accredited areas. Some retesting will be necessary, but the most difficult part of the eradication of tuberculosis in these areas has been completed, officials said.

New Naval Medical Center

A new naval medical center to function as a medical diagnostic and educational center under the control of the bureau of medicine and surgery has been established under a recent general order reported in the November *Military Surgeon*. The budget bureau will be asked to approve the expenditure of about \$3,200,000 for construction of a new naval hospital. If the appropriation is approved, work will commence about July 1. Capt Ulysses R. Webb has been ordered detached from command of the dispensary at the navy department to command the medical center, which replaces the naval hospital and naval medical school administration set-up.

Government Positions for Physicians

The U S Civil Service Commission announces open competitive examinations for two positions in the Children's Bureau, Department of Labor, and one in the Indian Service. Applications are invited for the positions of director of the division of maternal and child health and director of the crippled children's division in the Children's Bureau, each at a salary of \$6,500 a year. Applicants must have been graduated from recognized medical schools and in addition must have had certain specified experience. In the Indian Service the position is principal medical officer with a salary of \$5,600 a year. Applicants must have been graduated from recognized medical schools and must be licensed to practice in some state or the District of Columbia. In addition they must have had not less than five years experience in the vaccination of new-born infants with bacillin Calmette-Guérin vaccine according to the method of Calmette. They must also have had not less than three years experience in city, state or federal public health laboratories with work in tuberculosis. The two types of experience may run concurrently. Applications for all three positions must be filed not later than December 9. Full information may be obtained from the commission at Washington or from the secretary of the U S Civil Service Board of Examiners at the postoffice or customhouse in any city that has a postoffice of the first or second class.

Foreign Letters

LONDON

(From Our Regular Correspondent)

Oct 26, 1935

Reduction of the Noise of Vehicles

The campaign against noise, mainly traffic noise, and the formation of the Anti-Noise League have been described in previous letters. The government has been induced to take action by prohibiting the use of motor horns in cities at certain hours. But it has not stopped at this. The Ministry of Transport has appointed a committee to investigate the noise of road vehicles. It has measured the volume of noise made by motorcycles on the road. This foreshadows the time when every vehicle must comply with a certain maximum of measured noise. A new unit of noise, the phon, has been introduced. The noise of a subway train, with the windows open, has been measured at between 90 and 95 phons, which is the greatest noise that a car will be allowed to make in the future, if the committee's recommendations are adopted. The sound of a loud motor horn is represented by from 100 to 105 phons, of a pneumatic drill by 105 to 110 phons and of an airplane engine by 110 to 120. The greatest noise which the human ear can bear without pain is stated to be 130 phons. The adoption of this system of noise measurement and of a legal maximum noise for cars would be a considerable advance on the measures which the Ministry of Transport has taken to secure quieter streets, such as the enforcement of the use of pneumatic tires and the creation of silent zones. It has been hampered in the attempt to rid the roads of noisy vehicles by the fact that the "excessive noise," which is an offense, could not be measured but had to be left to individuals to decide what constituted this nuisance.

Acoustic tests were carried out by the committee on new vehicles with a noise meter designed to simulate the behavior of the human ear. The experiments showed that, while in general private automobiles made little noise, commercial vehicles were less satisfactory and motorcycles still more unsatisfactory. Tests with stationary vehicles showed that exhaust silencing of many motorcycles was unsatisfactory, while that of ordinary cars was satisfactory. Except at high speeds the ordinary automobile is not unduly noisy, but a number of sports cars are. Except at moderate speeds many motorcycles are too noisy. The committee has made the following recommendations: 1. When a vehicle is driven with full throttle at 30 miles an hour (or the maximum legal speed if that is less than 30), the loudness measured at a point 18 inches to one side of the vehicle shall not exceed 90 phons. 2. When the vehicle is stationary with the engine running at the speed that would give maximum power output, the loudness 18 inches behind the exhaust pipe shall not exceed 95 phons. The committee will continue its work under the chairmanship of Dr. G. W. C. Kaye. Among other matters that it is investigating is the noise made by the present type of motor horns.

The Training of Opticians

At the congress of the British Optical Association at Oxford Dr. Pistor, director of the Jena School of Optics, said that there was no longer room for the spectacle dealer who knew nothing about optics. The aim of the International League of Opticians was to raise the standard of the optical calling throughout the world. No one should be permitted any longer to style himself "optician" unless he had qualified by adequate study and training. He should at least be able to produce spectacles to conform to a given prescription and to make a frame according to prescribed measurements. He submitted the following schedule for the qualified opticians training: 1. Three years technical training under a qualified optician

in his workshop and showroom with technical examination. 2. Attendance at a school of opticians for supplementing his knowledge and for learning sight testing and prescription work, with a state-controlled examination at the end of the course. Professor Ronchi, director of the Royal National Institute of Opticians, Florence, said that Italy presented a paradoxical situation. Those who wanted to become opticians were compelled to pass an examination, and yet no schools had been provided where the necessary knowledge may be acquired.

The Fight Against Leprosy

At the conference of the mission to lepers held in London, Dr. Ernest Muir, medical secretary of the British Empire Leprosy Association, spoke of the antileprosy work in India. He said that, just as the home of tuberculosis was the great industrial towns, so the home of leprosy was the villages. Doctors and nurses might keep on for centuries treating those who attended the leprosy homes and dispensaries, but the disease would never tend to diminish, because its real source would remain in the villages. They must get into the villages. In Indian villages such work was proving wonderfully successful. The people were beginning to realize what the danger of leprosy is and what had to be done to prevent it. Dr. N. D. Fraser of the English Presbyterian Mission at Swatow, South China, spoke of his work in establishing outpatient leprosy clinics in country districts. In the Swatow district there were at least 10,000 lepers.

CONSULTANT SERVICES IN MUNICIPAL HOSPITALS

The municipal hospitals are maintained by the local authorities. Poor persons are entitled to free treatment, while those who can afford to pay something are assessed according to their means. The medical staff is a whole time one and of course is salaried. The medical staff of the voluntary hospitals, with the exception of the residents, who are all junior men, is not paid. Their recompense consists in the superior status conferred, which gives them consultant rank. But the municipal hospitals also appoint consultants and specialists for part time work, for which they are paid. As their whole time staff consists of men appointed for life, many of them are experienced physicians and surgeons, and the consultants and specialists are used for cases presenting special difficulties. The Manchester city council has made a new departure in the three large municipal hospitals, which together have 3,500 beds. At present twenty-six consultants have been appointed at a cost of \$22,500 per annum. They visit the hospitals once or twice a week. A new arrangement has been made which will cost \$62,500 per annum. The present system is held to be defective in that the patient is accorded specialist attention only when in the judgment of the medical officer in charge of the case a consultation is considered to be indicated. This is held to be wrong, because in the voluntary hospitals the visiting physicians and surgeons are responsible for the diagnosis and treatment of the cases and every patient is seen by a consultant soon after admission. The new scheme provides for increased frequency of the visits of consultants, who will be personally in charge of all the acute cases in the hospital. There will also be the closest collaboration between the municipal hospitals and the voluntary ones.

The appointment of consultants from the honorary staffs of the voluntary hospitals as a visiting staff to the municipal hospitals is not new, but giving them such increased responsibility and control is an innovation. The municipal hospitals at one time were little more than asylums for the aged and infirm poor. Now their scope is as wide as that of the voluntary hospitals and includes even the treatment of accidents. Some fears are entertained that they may supplant the voluntary hospitals. These used to be entirely supported by the voluntary subscriptions of the charitable, for the benefit of the poor. Now a charge is made according to the circumstances of the patient unless he is indigent. But this usually does not do more than

cover part of his cost to the hospital, so that subscriptions are still necessary. But with a complete hospital service now provided out of the public funds, the subscribers to the voluntary hospitals may decide that they are no longer necessary, especially in these times of excessive taxation, part of which is devoted to the support of the municipal hospitals. Here is another step in the socialization of medicine.

Oct. 18 1935

The Fourth French Gynecologic Congress

The fourth Gynecologic Congress was held at the Salies-de-Bearn thermal springs, June 8-10. It is the custom at a French medical congress to submit exhaustive surveys of the different aspects of one or two topics of current interest. The subjects and essayists are selected by vote at the preceding annual congress, so that the literature can be thoroughly reviewed and the personal experience of those selected to make the reports added. The subject chosen for this year's congress was "Genital Hemorrhages Exclusive of Those Incident to Pregnancy and Neoplasms."

The first paper was by L. and R. Dieulafoy of Toulouse on the "Vascularization of the Female Genital Tract." The authors' research has shown that a free anastomosis exists between the uterine and ovarian arteries. The intra-uterine anastomoses in the body of the uterus extend only to the midline. There is a rich anastomosis of the veins arising from the vagina, uterus, tubes and ovaries. There are but few valves in the veins. The latter anatomic condition and the free anastomoses between the veins explain the gravity of puerperal and postoperative thrombosis of the ovarian and uterine veins. In the uterine wall the veins begin as immense lacunae without evident intervacular spaces.

Paul Ulrich of Paris read a paper on "Genital Hemorrhages of Local Origin." Uterine hemorrhages can be grouped as menorrhagias and metrorrhagia. The term menometrorrhagia was proposed for cases in which one can no longer distinguish a menorrhagia and a metrorrhagia.

The ovary plays the principal part in endocrine disturbances of the female genitalia, it being understood that this organ in turn is under the control of other glands of internal secretion. Of the latter in the order of their importance, the hypophysis may be mentioned, then the thyroid, the islands of Langerhans and the adrenals.

The ovary elaborates the follicular hormone and the corpus luteum hormone. Ulrich is of the opinion, contrary to that of most authors, that there is no marked antagonism in the action of these two hormones. The corpus luteum hormone (progestin) is really complementary in its action to the follicular (estrogenic) hormone. The two hormones are so closely related from a physiologic and chemical standpoint that it seems difficult to conceive of a marked antagonistic action between the two. The term essential hemorrhagic metritis as suggested recently by some for the menometrorrhagias of ovarian origin ought to be dropped in favor of a division of such hemorrhages into (1) those in which there is a deficiency of the follicular factor, (2) those in which there is a hypersecretion of this principle in which case the secretion of the corpus luteum is deficient, and (3) those in which there is a hypersecretion of progestin. Douay and Champy have described the last group as "deciduoform hemorrhagic metritis."

In the discussion, Douay of Paris stated that his studies show that the abnormal persistence of the corpus luteum is accompanied by a hypertrophy and marked hyperemia of the uterine mucosa and an abnormal development of decidual cells just as if a pregnancy existed. In the hypertrophic form of metritis due to a follicular hypersecretion the determining cause is

the persistence of a follicular cyst. The menstrual period is delayed and then hemorrhages appear. The scrapings reveal a thick mucosa much less vascular than in cases of deciduoform metritis. In these cases the real lesion may be in the ovary or in the hypophysis. According to Douay the hypersecretion of the follicle stimulating, gonadotropic hormone is the cause of hypertrophic metritis of the second type described, while excessive secretion of the luteinizing hormone results in the deciduoform type of metritis.

Francillon-Lobre and Dalsace of Paris advocated the preliminary use of hysterosalpingography in obscure cases of metrorrhagia instead of blindly curetting every patient.

UTERINE HEMORRHAGES DUE TO SYSTEMIC BLOOD CONDITIONS

Emile-Weil and Isch-Wall of Paris read a paper on uterine hemorrhages due to systemic blood conditions. The blood dyscrasia which is found constantly in the course of uterine hemorrhages without local lesions is hemogenesis, the stigmas of which can be quite evident or obscure (fruste). The classic hemogenesis diathesis is characterized either by purpura or by hemorrhages from mucous membranes. The metrorrhagias observed before puberty are an example of the second type. The same is true of the menorrhagias and metrorrhagias of young girls, if local lesions can be eliminated. These include not only anomalies of excessive menstruation but also anomalies of rhythm such as hemorrhage every fifteen days or a menorrhagia on the thirty-fifth day. The phenomenon known as hemotrypsia is characteristic for hemogenesis. One sees a primary hemorrhage followed by others in more remote parts of the body. The menstrual hemorrhage can represent the primary one and be followed by others elsewhere. Control of such a primary hemorrhage is followed by cessation of the other hemorrhages. The evolution of a hemogenesis is characterized by alternate periods of cessation and recurrence in the form of attacks, which are dependent on various causes such as puberty, pregnancy, the menopause or various infections or intoxications. Every metrorrhagia should be investigated as to hepatic and endocrine disturbances and a search made for a possible hereditary syphilis.

The clinical forms of hemogenesis that are of particular interest are the metrorrhagias of a latent hemogenesis (form fruste), the diagnosis involving a search for the minor stigmas and the localized hemogenesis of the uterus, the constant recurrence and resistance of which to all treatment should arouse a suspicion of a systemic etiology. One must look for evidences of hepatic, splenic, medullary (bone marrow) or endocrine dysfunction to explain these metrorrhagias. The latter when accompanied by hirsutism or evidences of virility should lead one to suspect adrenal or hypophyseal dysfunction.

Treatment of Pyloric Stenosis of Infancy

At the April 9 meeting of the Pediatric Society of Eastern France, Rohmer of Strasbourg reported seventy-seven cases. There were eight deaths, but four of the patients were operated on too late, i. e. after failure of medical treatment. Of thirty-four infants operated on under favorable conditions four died, one each of operative shock, bronchopneumonia, peritonitis due to faulty technic, and incomplete division of the hypertrophied muscle fibers. In the forty-one cases in which operation was not performed there were also eight deaths, but here also four should be excluded because the infants were moribund when admitted to the hospital. Hence there were four deaths following medical treatment. The results of the two methods of treatment are about equal. Twelve of the patients who were operated on had been treated medically without success. In order to counteract the effects of the operation, sodium chloride solution in large amounts has been found to be efficacious. This rechlorination method is greatly in favor in France at present,

in postoperative treatment. Feeding can be begun within a few hours after operations for pyloric stenosis in infants. It is exceptional to find that vomiting persists during the first few days after operation. As to medical treatment, frequent feedings in small quantities, preferably with mother's milk as a base and plenty of water, are the chief features. If the vomiting continues after several weeks of medical treatment, immediate operative intervention is indicated. If one operates without waiting for the results of medical treatment, the mother may continue to nurse the infant.

Rohmer is of the opinion that the potential complications of medical treatment are by far more serious than the risks of operation. In mild cases one may try medical treatment, but in the more severe cases an operation should be performed as soon as possible. These more severe cases show on radiographic examination retention of the opaque medium over a period of several hours.

A second paper on medical treatment was read at the same meeting by Vonderweidt and Jullien of Mulhouse. They maintain that even severe cases can be cured by nonoperative treatment. Some may assert that these are simply cases of pylorospasm. The differential diagnosis of the latter from a hypertrophic pyloric stenosis is not easy and they doubt whether a hard and fast line can be drawn between the two conditions as there is a marked element of spasm in true hypertrophic pyloric stenosis. When incoercible vomiting long after taking food and even just preceding feedings, visible peristalsis and a palpable tumor are present, the diagnosis of hypertrophic stenosis is certain.

The medical treatment aims to combat the faulty nutrition, the pylorospasm and the diminution in blood chlorides. Preference is given to breast milk. If this is not feasible, milk powder or cow's milk coagulated with a special ferment is given, as well as carbohydrates with plenty of sugar. The infant should be fed every two hours and in small quantities. Salt is added to each feeding to counteract the chloropenia. Dextrose solution by the drip method is given by rectum, about 50 cc from four to six times in twenty-four hours. For the pylorospasm a drop of a 1:1,000 solution of atropine sulphate is given with each feeding. The excessive gastric peristalsis is greatly relieved by hot applications. If the vomitus contains much acid material, gastric lavage is done, once daily, with a mild alkaline solution. Of twenty-eight cases thus treated twenty-three were cured. Three of the five deaths occurred before 1930. Since 1931, when salt was added to the feeding, eighteen cases have been cured and there were only two deaths. In both of the latter the infants were markedly cachectic when first seen.

In the discussion, Bindschiedler of Strasbourg emphasized the importance of adding sodium chloride to make up for the loss of chlorides.

Exophthalmos in Acromegaly

Exophthalmos is a symptom of certain diseases of the hypophysis and is seen especially in cases of acromegaly, according to Marcel Labbe and Justin-Besançon, who reported such a case at the July 5 meeting of the Société médicale des hôpitaux. The protrusion of the eyeballs resembles completely that seen in severe hyperthyroidism. In their case this symptom appeared three years before the first skeletal evidences of acromegaly, hence in the early stages of the latter the exophthalmos may be readily thought to be of thyroid origin. In the later stages of acromegaly the protrusion of the eyeballs can be masked by changes in the bones surrounding the eye. Experimentally, the exophthalmos observed in acromegaly can be reproduced by injection into guinea-pigs of the acid portions of the anterior hypophyseal lobe. Exophthalmos follows injection of anterior pituitary into thyroidectomized animals.

In the discussion, Azerad called attention to his paper on the difficulties of differential diagnosis between exophthalmic goiter

and acromegaly. A goiter may be one of the first observations in acromegaly. If the goiter is associated with a rise in the metabolic rate, an erroneous diagnosis of hyperthyroidism may be made.

Staphylococcus Anatoxin in Treatment of Sepsis

A man, aged 25, who had an infection of a relatively minor wound, became seriously ill. A high temperature, jaundice, osteomyelitis of the tibia and the jaw, and a pulmonary abscess, in the pus of which *Staphylococcus aureus* was found, appeared within a short time. At the July 5 meeting of the Société médicale des hôpitaux, Robert Debre and his associates reported such a case. The blood culture was positive for the organism and on account of the rapid increase in the signs of a pyemia the prognosis became decidedly unfavorable. 160 cc. of an antistaphylococcus serum prepared by Ramon at the Pasteur Institute was injected without any appreciable improvement. Then the injection of a staphylococcus anatoxin, also prepared by Ramon, was begun. Four doses were given over a period of six weeks. The amounts employed were respectively 0.75, 1.5, 3 and 4 cc. A marked improvement in the general condition was noted after the third injection, but an empyema containing the same organism developed, which required drainage. Nevertheless, the patient recovered.

The authors call attention to the fact that the examination of the blood showed a constantly higher content of staphylococcus antitoxin following the injections of anatoxin. This is confirmed by the observations clinically and in animals of a marked antitoxic immunization following the injection of staphylococcus anatoxin. This antitoxic immunity is accompanied by an antimicrobial immunity in animals. An antitoxic vaccination and an equally efficacious antitoxic serotherapy can now be achieved in staphylococcus pyemia.

Surgical Treatment of Pulmonary Tuberculosis

The surgical treatment of pulmonary tuberculosis was the subject of a number of papers read at the eighth National Tuberculosis Congress, held at Marseilles in April. The first paper was by Leuret and Caussimon of Bordeaux on the "Indications and Results of Extrapleural Thoracoplasty." Every center in which pulmonary tuberculosis is being treated should have a surgical service in which thoracoplasty can be performed. An effort should be made to avoid extensive operations for relatively slight lesions. The chief aim should be to adapt the plastic operations to the subjacent foci, in other words, to collapse the bony thorax only where locally indicated. The use of radiography and injections of iodized oil is the best guide as to how much one can accomplish by resection. As an anesthetic, tribrom-ethanol with the addition of small amounts of ethyl chloride, seems to be the best agent. Even with every possible precaution, thoracoplasty must still be considered a serious procedure. Of ninety one personal cases 80 per cent were benefited. Of this number, 40 per cent may be considered as clinical cures. In 20 per cent of the ninety one cases the result was a failure. The following cases call for operation: (a) those in which pneumothorax is indicated but is impossible owing to obliteration of the pleural space by adhesions, (b) cases in which a pneumothorax has been done but is unsuccessful because of a pleurisy, which either follows the pneumothorax or occurs spontaneously or in which an intercurrent infection leads to a recrudescence of the tuberculous involvement of the collapsed lung.

The important chapter in thoracoplasty is formed by adherent apical lesions, that is, cavities which are inactive with little secretion. Large cavities due to active lesions and necessitating extensive resections are a contraindication to operation. Such cavities can be treated by thoracoplasty after good drainage has been provided for as a preparatory measure. Tuberculous pleurisy with fistula formation is an unwelcome clinical entity and one should not wait too long before attempting a thoraco-

plasty lest the greatly thickened pleura endanger the success of operative intervention. A thoracoplasty should be done only after treatment at a sanatorium and only in patients who do not have dyspnea on exertion and permanent tachycardia. Preliminary phrenicectomy is not indicated.

Maurer and Rolland of Paris in their paper on the same subject stated that the principal indication for artificial pneumothorax is a recent bronchopneumonia of tuberculous origin. It is dangerous to continue to employ the method if it is not successful in loosening up adherent bands between the two layers of the pleura. In such cases phrenicectomy or better still, a thoracoplasty should be done. The former should be performed only if there is much chance of its being a success. A phrenicectomy should not be considered as a necessary preliminary to a thoracoplasty. As to results, these varied according to whether the thoracoplasty had been performed in sanatoriums or in private and public (Paris) hospitals. The mortality in 278 thoracoplasties was only 0.78 per cent.

Professor Guéniot Dies at Age of Nearly 103

An eminent obstetrician of Paris Professor Guéniot, has passed away at the age of 102 years and 8 months. His hundredth birthday was celebrated at a special meeting of the Academy of Medicine, of which he was elected a fellow in 1880 and president in 1905. He was active until a short time ago and engaged in writing his memoirs. In announcing the death of Professor Guéniot, Sireday, the president of the Academy of Medicine, described the excellent work of the deceased in his specialty, obstetrics, and his noble character which made Guéniot a worthy representative of the tradition of medical honor in the highest interpretation of the term.

Incidence of Venereal Diseases and Prostitution

The federal census of venereal patients, taken in 1934, reveals, on the basis of replies to questionnaires sent to physicians and institutions, that in the civilian population there were 12,499 male and 6,587 female patients who received their first treatment during the month in which the census was taken. Hence the annual number of new venereal patients may be placed at 225,000, as compared with 370,000 in the last census year (1927). Therefore, the new cases of venereal disease in 1934 included 47 males and 23 females to each 10,000 of population. There were about 10,000 new cases of gonorrhea and 4,000 new cases of syphilis. The number of new cases of gonorrhea in men was almost three times as great as the number reported in women. About sixty men and a like number of women reported to a physician, during the census month, by reason of two venereal diseases while one man had a triple involvement. About one third of the patients during the census month, sought medical aid of a general practitioner, more than 50 per cent consulted specialists and about one sixth were admitted to hospitals. The decline in the number of new cases as compared with 1927, is reflected in all the morbid types. In general, there was an earlier beginning of treatment in gonorrhea, which is gratifying although the number of cases not treated until the chronic stage was reached (especially in women 18 per cent) is still much too high. Of importance is the early detection of syphilis, particularly among the juveniles since in that group and, to some extent, also among the older men contagion appears to have increased. If 225,000 persons are treated for venereal disease annually in Germany it is evident that of 100 male persons between the ages 15 and 49 about twenty five are treated by a physician by reason of venereal disease the percentage of women so treated is about 12. In the larger cities the danger of infection is often more than twice as great as in the smaller towns.

Interesting observations on the medical supervision of prostitution have been published by Dr Morschhäuser of Cologne. The number of prostitutes regularly supervised by the Cologne board of health is twice as large as formerly, during the period of regimentation, and ranges around 1,200. In recent years the number of voluntary requests for registration has greatly increased. In Cologne the supervision of prostitutes is effected by means of a system that deals with the problem in an individual manner. There are no general provisions with regard to the frequency with which prostitutes must be examined; the intervals range from one to fourteen days, depending on individual conditions. During the beginning period of control the homes of newly registered prostitutes are inspected, in order to determine their hygienic condition. This system of supervision carried out on the basis of individual needs has a salutary effect on the general conduct of the women, as they want to be classed in a higher group, with longer intervals between the stated examinations. Also with respect to women who are regularly examined by a special physician, every fourth examination must be made at the headquarters of the board of health. It is an established principle that these women shall not be given a certificate as to their condition of health. The cards issued by the board of health contain the words 'No guaranty as to condition of health'. Nor are specialists permitted to supply any attest designed to strengthen the evidence furnished by the card issued by the board of health. If any such woman is found on examination to have an infectious venereal disease, it is mandatory that she be sent at once under proper escort to a suitable hospital for treatment.

For the purpose of facilitating search for sources of infection, the board of health has created at headquarters the following special filing cabinets: (1) a complete list of the names of all registered prostitutes, together with photographs, (2) a list of prostitutes arranged according to streets, (3) a list of all the nicknames and pet-names by which prostitutes are known, and (4) a list of all the persons who have become known to the board of health in any connection. These files prove valuable if the infected person cannot give any details concerning the person in question. If a prostitute is discovered to be a source of infection she is immediately escorted from her home by a special official, in order to prevent further contagion and any possibility of her escaping to another city. In the case of infected children, special care is taken to discover the source of the infection. Venereal persons dismissed from a penal institution are taken directly to a hospital, if they have no fixed abode or are known to be asocial and unreliable.

Dr Schoen of Berlin has published statistics on the combating of venereal diseases in connection with disability insurance. In 1933, 11,480 requests for treatment of insured persons and members of their families were received, and about 85 per cent of the requests were granted. Treatment was given to 9,109 insured persons (1930, 30,614). 6,741 of whom were men (1930, 20,534). Syphilis patients numbered 4,212, gonorrhea patients 3,712, 109 patients were infected with both diseases. The number hospitalized was 1,154 (686 men 468 women). Of 8,684 persons treated, a complete cure was effected in 8,513 or 98 per cent. Among the patients there were 1,849 married men and 577 married women. The average cost of treatment for a hospitalized person was 189 marks (\$75), in 1930 the average cost of treatment was much higher (242 marks, or \$97). The average cost of ambulant treatment was 52 marks (\$20) in 1930 78 marks (\$31). The total expenditures for individual treatment amounted to 635,000 marks (\$250,000), in 1930 3,100,000 marks (\$1,240,000). In 1933 the financial situation affected disability insurance to such an extent that it was found difficult to measure up to former performances with regard to the treatment of patients with venereal disease, but care was taken not to cripple the functioning of the consultation centers. Welfare work among noninsured venereal patients was

restricted to 454 persons, whereas, in 1930, 5,663 persons who were uninsured were given treatment. The total expenditures for the consultation centers (which were able to keep expenses down by utilizing in some instances the consultation centers of other organizations) amounted to about 880,000 marks (\$350,000), as compared with 1,900,000 marks (\$760,000) in 1930.

The Deutsche Gesellschaft zur Bekämpfung der Geschlechtskrankheiten published an officially approved leaflet for distribution by physicians among venereal patients, in accordance with legal provisions pertaining thereto. During the past six years a total of 650,000 of these leaflets has been distributed. It is apparent, therefore, that only about 36.5 per cent of the persons receiving first treatment for a venereal infection were given this official leaflet.

MADRID

(From Our Regular Correspondent)

Oct. 11, 1935

International Congress of the History of Medicine

The tenth International Congress of the History of Medicine, organized by a committee of which Dr. Javier Cortezo was chairman, was held in Madrid, September 22-28. Dr. Gregorio Marañón was the president. More than forty-five countries and a large number of medical societies sent delegations. There were the following delegates: Drs. Diepgen from Germany, Max Neuburger of Vienna from Austria, Tricot-Royer from Belgium, Laignel-Lavastine and Guart from France, Giordano and Capparoni from Italy, and Edgar Erskine Hume, Howard Dittick, Edward B. Krumbhaar and Henry E. Sigerist from the United States. The official topics were Arabic medicine in Spain, medicine in America during its discovery and colonization, and medical folk-lore in civilized countries. The official reunion of the delegates took place September 22. Dr. Laignel-Lavastine read an oration in memory of Drs. Jeanselme, Garrison and Menetrier, deceased members of the congress. Dr. Marañón discussed the proposed establishment of an institute of the history of medicine and of a branch of the International Society of the History of Medicine in Spain. Ceremonies for the opening of the exhibition of the congress followed. Collections of instruments, books, electrical apparatus, illustrations of medical treatments, drugs, paintings and other items showing the evolution of medicine and its branches from its early life up to the present were exhibited. The most important collections were those sent by the Wellcome Laboratories of London and by several faculties and academies of medicine and pharmacy and by some national libraries. A general reception marked the end of the evening.

The opening of the congress took place in the Hospital de la Santa Cruz, in Toledo, September 23. Addresses were made by the minister of public education, who represented the president of Spain, by the general secretary of the congress, Mr. Oliver, by the delegate from Italy and by the president of the congress, Dr. Marañón. Receptions were given to the delegates before their return to Madrid, and festivities were held in their honor.

The first plenary session was held September 24. Dr. Capparoni presented an address on Arabic medicine in Spain at the end of the thirteenth century. Dr. Guart spoke on the Persian origin of Arabic medicine. Dr. Angelica Panayotatou, a teacher of hygiene in Alexandria, spoke on the role that both the teachings and the books of Abulkasim (1110 A. D.) and of Averroes (1126-1198) and the many translations of Arabic medical works into Spanish had in the dissemination of medicine in Europe. The Spanish-Arabs of the tenth and eleventh centuries, because of their frequent voyages to the eastern regions of Europe, learned about new methods of treating diseases, new drugs and the preparation of aromatic waters.

Hospitals and reading rooms existed in Spain by that time. The city of Cordoba had fifty hospitals and a library with about 225,000 books, and the rights of the insane to be treated with humanitarianism and the performance of inhalation anesthesia were known by that time. Dr. Bravo spoke on Mohammedan hospitals, physicians and quacks during the reign of Philip II. Dr. Goyanes presented to the audience his translation of Abulkasim's surgery. He made an address in Latin on the importance of the books in the exposition and their meaning to the history of medicine. After the session, the delegates attended the inauguration of the memorial room to Cajal, which contains his death mask, his desk, his microscope and his medals and prizes.

The second session was held September 25. Dr. De Silva Carvalho spoke of medicine at the time of the discovery and colonization of Brazil. Brazilian medicine developed especially from the teachings of a group of Jewish physicians who came to Brazil with the fleet of Pedro Alvarez Cabral and acquired extensive knowledge of diseases of natives and immigrants. Dr. Borzone of Argentina gave a biographic sketch of Manuel Rodriguez de Montonera and emphasized his work on leprosy, that this physician carried on. Dr. Bazzocchi of Italy spoke on medicine and surgery in Peru before the Spanish conquest. Native Peruvians knew something of the therapeutic properties of the fauna, flora and minerals of their soil. The speaker reviewed the history of the treatment of seta and verruga, two native diseases. Dr. Clavijero said that physicians of the old Spanish navy deserve the priority for the administration of vaccination in America.

In the afternoon the delegates were tendered a banquet at the Museo Naval, where they heard lectures on sanitation in the navy and were shown old charts of Spanish explorers and old documents of physicians in the fleets, in which the unhealthful results of feeding the crew with rice were pointed out. In the evening they attended an official reception at the palace of the ministry of foreign affairs.

At the third session, September 26, the topic of medical folk-lore was discussed. Dr. Laignel-Lavastine said that it has both theoretical and practical value. It clarifies several of the factors involved in the evolution of human civilization. Medical folk-lore can be classified into three groups: ethnic, magical and religious and popular folk-lore. It originates in psychologic factors and develops in social factors. Dr. Castiglione reviewed the myths of the medical Italian folk-lore and marked the points of its differentiation from the folk-lore in other countries. Dr. Borzone of Argentina spoke about the method of cutting hair short as a folk-lore method in the prevention of exanthematous typhus in Argentina and he sang popular folk-lore songs, accompanied at the piano by Professor Sphurca. Drs. Karn, Comrie and Sixto spoke on medical folk-lore in Hungary, Scotland and the Philippine Islands, respectively. Dr. Castiglione spoke on the role of the old civilization of the Mediterranean races in the development of medicine. These races inherited the civilization of ancient countries through the Greeks, Romans and Arabians. Arabian Italians and Arabians played an important part in the development of medicine, first in Europe with Galen in Italy and Maimonides in Spain, and then by the discovery of America and colonization. Dr. Gomori spoke on folk-lore in the Balkan countries. Medical folk-lore was an obstacle to the progress of medicine and yet certain folk-lore methods were the basis for scientific studies that resulted in advances in medicine. Bathing originated among the people who lived near the Aegean sea. Rumanians used petroleum as a curative agent and they used the fat of bears for stimulating the growth of hair. There was a suspicion in some oriental countries that malaria was caused by an organism that lived in ponds. Dr. Stoianoff spoke on medical folk-lore in Bulgaria. His interesting article appears in the proceedings of the congress. Dr. Sigerist, direc-

tor of the Institute of the History of Medicine at Johns Hopkins, said that medicine is a social science. Its history should be studied from the sociological and economic angles. The treatment and care of patients are only the means through which medicine obtains its aim, the restoration of healthy individuals to society. The application of medical knowledge is related to social and economic conditions. The members of the Johns Hopkins institute are attempting to establish a new branch of medicine, medical sociology, through which the relations between patients and physicians can be more clearly understood. Dr Decref of Madrid spoke on the hospital for traumatic cases in the Escorial in 1563 and of its role in the development of surgery, and the treatment of fractures in Spain. Dr Hyman I. Goldstein of Camden, N. J., spoke on the priority of Italian physicians in the introduction of liver therapy in anemia. Drs Castellini and Pirera of Naples reported in 1910 and 1912 the results of their work in administering liver extract to patients with anemia. Minot, Murphy and Whipple were unaware of these reports. Dr Felix Martí Ibañez of Barcelona spoke on miracles. There are two large groups of performers: those who pretend to read the stars and those who cure by psychoanalysis, hypnotism, suggestion, chromotherapy, phonotherapy and other methods. In both groups the performers are only exploiters of the faith of the patient. The speaker reviewed the history of the mystical physiology and psychology of India.

At the fifth session, September 27, the delegate from the Philippine Islands spoke on the evolution of medicine and medical folk-lore. Dr Manuel Villaverde reviewed the history of medicine in Cuba, where before the Spanish conquest the natives considered digestive disturbances the cause of all diseases. Drs Guisan and Royo Villanova spoke on medical folk-lore in Switzerland and in the province of Aragon, respectively. Dr Laignel-Lavastine read a paper by Dr Torkoiman on the history of the Sigüenza pharmacy, which was established in 1664. Dr Capparoni spoke on Diego Alvarez Echance, a Spanish physician who accompanied Columbus on his second voyage to America. Dr Javier Cortezo, organizer of the congress and director of *El siglo médico*, gave a biography of Dr Juan Sorapan de Rieros. Dr Francisco J. Blanco Justo delivered an address on the relations between botany and the development of Arabian medicine. Dr Ramiro de Rinedo gave a biography of Saint Isidore, who was a teacher of medicine in Europe in the seventh century.

At the final session, September 28, Dr Reichson emphasized the influence of Galen and his school on the evolution of Scandinavian medicine. Dr Alfonso de la Peña reviewed the evolution of transureteral surgery. Dr Max Neuburger of Vienna gave a biography of Dr Gomez Pereira, Spanish philosopher and physician of Philip II. Dr Isidro de la Villa of the University of Valladolid reported on the ordinances of physicians and pharmacists during the time of the Catholic kings. Dr Sanchez de Rivera spoke on the work of the Spanish physicians of the fifteenth and sixteenth centuries. A visit was paid by the group of Rumanian physicians to the monument erected in the Military Hospital Carabanchel in 1929 to the Spanish physicians who died at Morocco.

The following conclusions were approved. The articles read during the tenth International Congress of the History of Medicine proved that Arabian-Spanish medicine inherited the Greek and Roman civilization and that Spain was the source of dissemination of medicine to the oriental countries; that the civilization of the Latin races had a great influence on the evolution of science and medicine in South America after the colonization in those countries and that medical folk-lore is of importance for the critical study of the origin of civilization and of medicine. It was resolved that further studies on medical folk-lore be made by a committee of members of the International Society of the History of Medicine. The priority of

Carlos Finlay in the discovery of the transmission of yellow fever was proposed and accepted amid applause. A reception and dance was held September 29.

Personal Items

The Gran Cruz del Merito Militar, the highest medal in the Spanish army, has been awarded to Dr Mariano Gomez Ulla for his work as a surgeon in the army. Dr Gomez Ulla is very popular. Members of the parliament voted unanimously to give him the medal.

Two statues were recently unveiled: a bust of Dr Garcia Tapia, professor of otorhinolaryngology at the Faculty of Medicine of Madrid, and a bust of Dr Jose Luis Lopez de Haro. Dr Garcia Tapia's bust was unveiled at Riaza, Segovia. Dr Lopez de Haro's bust was unveiled in Almaden de Minas, a center of mines of mercury. Both physicians are still living.

A ceremony took place in the old University of Alcalá de Henares, September 29, at which the degree "Doctor ad honorem" was bestowed on Drs Max Neuburger of Vienna, Tricot-Royer of Brussels, Howard Dittick of Cleveland, Ohio, Victor Gomiou of Bucharest, Laignel-Lavastine of France, David Giordano of Venice, Pablo Diepgen of Berlin, Reichborn Kjennerud of Oslo and Humphry Rolleston of London.

TURKEY

Oct 14, 1935

The National Medical Congress

The sixth Turkish National Medical Congress has just closed. The sessions of the congress were opened with an address by Premier General Ismet İnönü in which he rehearsed the sacrifices Turkey had made and the efforts put forth in the campaign to control the drug traffic. He concluded with a recommendation that the medical profession continue its efforts to make similar progress in combating the evils of alcoholism and in seeking new light on the understanding and treatment of disease.

Besides the addresses scheduled on the regular program there were addresses by representatives of the Soviet Medical Association who were present as guests of the congress.

Two main subjects for discussion had been chosen. The first was alcohol and other intoxicants. The congress went on record without a dissenting voice, as being in favor of having the government take vigorous steps to control and limit the use of alcoholic beverages. The American experiment in prohibition and its apparent failure were frequently mentioned, but there was a feeling that a similar experiment would probably meet with more success if it was undertaken in Turkey. Dr Fahrettin Kerim Gökay, the general secretary of the association, summed up the discussions on this question. His closing words are noteworthy. He said that though the profession realized that it would have to make progress slowly and in the beginning would probably have to be satisfied if the use of rakı could be limited, it was to be clearly understood that the ultimate goal was absolute prohibition.

The other main subject was rheumatism. The discussions following reports on this subject were so prolonged that a number of papers on miscellaneous subjects that were to have been read on the last day had to be omitted. Emphasis was laid on the value of physical therapy in chronic rheumatic disease and the need of further study along these lines.

The congress prepared a splendid health exhibit for the general public. The various acute contagious diseases, with the method of spread, incubation period, early signs and symptoms were illustrated by pictures, casts, models, and short, vivid sentences. Each disease was presented in a separate booth and the need of skilled medical care for each was emphasized. The subjects were so simply and carefully presented that the information could reach the simplest villager.

In a similar manner the work and progress of the national school for the deaf and blind and of the commissions for the control of tuberculosis, malaria and venereal disease were presented. It is a highly educational exhibit and is to remain open to the public for some months. In the meantime, efforts are being made to get together similar material for a portable exhibit, which can be taken into the villages.

At the closing session of the congress the subjects of hygiene and grip were chosen as the main subjects for discussion at the seventh congress to be held in Ankara in 1937.

ITALY

(From Our Regular Correspondent)

Sept 15, 1935

Problems of Higher Instruction

Problems pertaining to higher instruction have been considered of late by parliament. In the chamber of deputies the minister of public instruction announced that, in some twenty Italian universities, clinics and scientific institutes, all well equipped, have been created, which has required an outlay of about 600,000,000 lire, or \$48,000,000.

Zingale spoke on academic freedom in teaching at Italian universities and on the custom of granting the *venia legendi* in medicine to *privatdozents*. According to the speaker, in recent years the number of *privatdozents* that have been appointed has been large.

In the senate, Professor Giordano recommended a more extensive practical preparation for physicians, who often present themselves for the 'state examination' too soon after graduation from the university. The speaker expressed the view that the *venia legendi* should not be granted to the physician who merely furnishes evidence of having specialized in a given branch of medicine but should be reserved for the physician who demonstrates, at the same time, that he has delved deeply in all the related general sciences.

Senator Maragliano expressed the belief that the minister of public instruction should exercise greater influence in the appointment of university professors than at present. He said also that the instruction in the faculties of medicine is organized on the basis of too doctrinal conceptions, whereas it should be coordinated on the basis of the positive finalities of the studies.

The Academy of Medicine of Turin

Before the Academy of Medicine of Turin Professor Ribeiro of Rio de Janeiro discussed the value of finger prints in legal medicine. Leprosy, he observed, destroys completely the finger prints. This alteration occurs in about 80 per cent of the cases, not only in patients who present nerve lesions but also in those in whom the hand shows no apparent lesions. In the latter cases white lines are observed that cut transversely the figures formed by the papillae, so that it may prove possible to establish an early diagnosis of leprosy dactyloscopically in suspected cases. In the right hand of patients with scleroderma the speaker has observed frank changes that present an entirely different aspect from those of leprosy. Radiologists also develop not infrequently lesions affecting the finger prints. Professor Ribeiro said in conclusion that dactyloscopy preserves nevertheless its medicolegal value, it being impossible to change a finger print or to confound it with another, and even the pathologic lesions constitute a new means of identification.

Petit of the Pasteur Institute of Paris, reported his research on the method of preparing serum with which to combat *Leptospira icteroides*. He observed some similarity between these observations and those characteristic of anterior poliomyelitis and hence he holds that in the spinal cord of patients with poliomyelitis there is a previously unrecognized organism. On injecting a horse with the spinal cord tissue of an animal that died from poliomyelitis, he obtained after three months, serum that had the property of combating the virus of poliomyelitis.

The serum is prepared, at the Pasteur Institute, by the use of the spinal cord tissue of monkeys that have died from poliomyelitis, in about 70 per cent of the horses that are injected in the preparation of the serum there is no production of mumps. The serum has been in use for about fifteen years. The results secured may be summarized thus. If the serum is injected in the preparalytic stage, neither paralysis nor paresis develops. The serum cures the paralysis in a large number of adults but not in children and reduces the mortality about one half.

Visit of French Physicians

A committee of French physicians came to Italy recently to study the application of the law pertaining to compulsory insurance against tuberculosis. They visited first the sanatoriums and the hospitals of Lombardy. They then continued their journey to Rome, where they visited the Carlo Forlanini Institute for the study of tuberculosis. At the Bernardo Ramazzini Sanatorium, Professor Bocchetti explained his ideas concerning postnatorial treatment. The committee visited also the Istituto di igiene e sanita pubblica, the Istituto per lo studio e la cura del cancro, and the Scuola superiore di educazione fisica.

The Public Health Service

Prof. Gianni Petragiani, of the chair of hygiene at the University of Siena, has been appointed "director general" of the public health service.

Prof. Dante De Biasi, academician of Italy, has been appointed director of the Istituto di sanita, a new institute that comprises laboratories of microscopy and bacteriology, as applied to hygiene, laboratories of chemistry, physics and sanitary engineering, a laboratory for biologic researches on the use of opotherapeutic products, a laboratory for investigations on the diffusion and the prophylaxis of malaria, and a laboratory for researches on epidemiology and the prevention of infectious diseases.

Retirement Age for University Professors

To speed the introduction of new blood in the schools and make the conditions of the instructing personnel correspond to those recently established for all civil functionaries, the ministerial cabinet has approved the draft of a law that would reduce by five years the age limit for the compulsory retirement of university professors (at present 75 years) and of school principals and teachers (at present 70 years). The decree will go into effect this year but those who have to leave the service earlier than they anticipated will be allowed certain concessions. For example, in order that teachers may attain the length of service (forty years) necessary to secure the maximum pension, time spent in the supply service will be counted in full.

Marriages

- MARTIN CARL LINDMAN, Rockford, Ill., to Miss Alice Dorothy Port of Youngstown, Ohio, September 2.
 RUBIE M. DURGIN, Berkeley, Calif., to Mr. Andrew B. McKinne of San Francisco, September 14.
 BEVERLY WILKINS NASH to Miss Frances Lucille Bowers, both of Timberville, Va., September 1.
 RICHARD W. TERRILL, Indianapolis, to Miss Frances Brelly of Lawrenceburg, Ind., in September.
 RALPH J. MCQUISTON, Indianapolis, to Miss Barbara Douglas of Franklin, Ind., September 7.
 ALFRED CURTIS ORMOND JR., Zanesville, Ohio, to Miss Anne Shingluff of Cambridge recently.
 THEODORE CAMPBELL THOMPSON, to Miss Cornelia Tomlin, both of New York, August 17.
 EDWARD FRANKLIN BLAND, Boston, to Miss Frances Pomeroy of Winchester, September 7.
 LAWRENCE N. HOST to Miss Gertrude Casey, both of Detroit, September 4.

Deaths

Felix A Larue ♂ New Orleans, Tulane University of Louisiana Medical Department, New Orleans, 1889, in 1898 lecturer and clinical instructor in general operative surgery, including applied anatomy and orthopedics, New Orleans Polyclinic, and in 1900 appointed professor of operative surgery and applied anatomy, when the New Orleans Polyclinic was taken over by Tulane University in 1906 he was given the rank of professor of operative and clinical surgery, in 1924 was made professor emeritus, secretary and treasurer of the Louisiana Board of Medical Examiners, 1905-1910, for many years physician for the French consulate, and in 1913 was awarded the *Officier d'Instruction Publique* by the French government, for many years a member of the board of directors of the Mercy Hospital and St Mary's Orphan Asylum, aged 70 died, October 5, in the Touro Infirmary

Morgan Smith ♂ Little Rock, Ark., Arkansas Industrial University Medical Department, Little Rock, 1889, Tulane University of Louisiana Medical Department, New Orleans 1904, member of the House of Delegates of the American Medical Association, 1912-1914, professor of pediatrics and formerly dean, University of Arkansas School of Medicine, past president and secretary of the Arkansas Medical Society, at one time member of the state board of health and state health officer, member of the American Academy of Pediatrics, fellow of the American College of Physicians on the staffs of the Little Rock General and Baptist State hospitals and St. Vincent's Infirmary, aged 67, died, September 14, of arteriosclerotic heart disease

Daniel Kerfoot Shute ♂ Washington, D C., Columbian University Medical Department, Washington D C., 1883 professor emeritus of clinical ophthalmology, George Washington University School of Medicine and formerly prosector to the chair of anatomy, lecturer, and professor of anatomy past president of the Medical Society of the District of Columbia, member of the American Academy of Ophthalmology and Otolaryngology and fellow of the American College of Surgeons, on the staffs of the Providence Hospital, Central Dispensary and Emergency Hospital, Columbia Hospital, St Elizabeth's Hospital and the George Washington University Hospital, aged 76, died suddenly, October 21, of arteriosclerosis and coronary thrombus

Albert Edward Roussel ♂ Philadelphia, Jefferson Medical College of Philadelphia 1882, emeritus professor of medicine, University of Pennsylvania Graduate School of Medicine formerly associate professor of practice and clinical medicine, Medico-Chirurgical College of Philadelphia, fellow of the American College of Physicians, awarded *Officier d'Academie* and *Chevalier de la Legion d'Honneur* formerly physician to the French and the Argentine consulates aged 72 died, November 2, in the Graduate Hospital of the University of Pennsylvania, of heart disease.

Peter Conover Field ♂ Colonel U S Army, retired, Pasadena, Calif., College of Physicians and Surgeons Medical Department of Columbia College, New York, 1895 fellow of the American College of Surgeons, entered the regular army as an assistant surgeon in 1901, was appointed a captain in the medical corps in 1906 served during the World War in 1927 was made a colonel retired in 1932 for disability in line of duty, aged 65, died, September 9

John McCabe ♂ New York, Columbia University College of Physicians and Surgeons, New York 1902 formerly professor of internal medicine New York Polyclinic Medical School and Hospital and instructor of pediatrics, Bellevue Hospital Medical College aged 57, on the staffs of the New York City Hospital, Jewish Memorial Hospital Long Beach Hospital and the Midtown Hospital where he died October 7, of cerebral hemorrhage.

Cosam Julian Bartlett ♂ Colonel U S Army, retired, Santa Cruz, Calif., University of California Medical Department, San Francisco 1898 entered the regular army as an assistant surgeon in 1901, was appointed a captain in the medical corps in 1906 and a colonel in 1927 served during the World War, retired in 1934 for disability in line of duty, aged 61 died, September 7, in Los Angeles, of coronary occlusion and myocarditis

Charles Parsons Gildersleeve, Port Jefferson, N Y College of Physicians and Surgeons Medical Department of Columbia College, New York 1881, member of the Medical Society of the State of New York, fellow of the American College

of Surgeons, consulting surgeon to St Peter's Hospital, Brooklyn and St. Anthony's Hospital, Woodhaven, N Y, aged 75, died, September 28 of coronary heart disease

Clarence Carl Pflaum, Duluth, Minn., University of Minnesota Medical School, Minneapolis, 1930 member of the Missouri State Medical Association, formerly assistant professor of pathology University of Missouri School of Medicine Columbia aged 35 on the staff of St Luke's Hospital, where he died September 10, of suppurative otitis media, cerebral abscess and secondary meningitis

Heinz Langer, Pittsburgh Friedrich-Alexanders-Universität Medizinische Fakultät, Erlangen, Bavaria, Germany, 1917, member of the Medical Society of the State of Pennsylvania and the American Roentgen Ray Society, served during the World War, aged 47 on the staff of the Western Pennsylvania Hospital, where he died, September 28, of pneumonia

Robert George William Dalby, Ann Arbor, Mich., University of Michigan Medical School, Ann Arbor, 1931, member of the Michigan State Medical Society, instructor in obstetrics and gynecology at his alma mater, on the staff of the University Hospital, aged 29, killed, September 29, in an automobile accident near Northville.

John Francis McEncroe, Schenectady, N Y, College of Physicians and Surgeons, Medical Department of Columbia College New York, 1887, an Affiliate Fellow of the American Medical Association, for many years city physician and police surgeon, aged 74, on the staff of the Ellis Hospital, where he died October 2

Rachel A Watkins Long, Holdrege, Neb., College of Physicians and Surgeons of Chicago, School of Medicine of the University of Illinois, 1906 member of the Nebraska State Medical Association, secretary and past president of the Phelps County Medical Society, aged 55, died, September 29, of carcinoma

Solomon Garfield Smelser, Liberty, Ind., Medical College of Indiana, Indianapolis, 1905 member of the Indiana State Medical Association formerly member of the state board of medical registration and examination, served during the World War aged 55 died, September 16, of sarcoma

Thomas Bernard McQuaid, Everett, Mass., Dartmouth Medical School, Hanover, N H, 1896 member of the Massachusetts Medical Society, member of the local board of health on the staff of the Whidden Memorial Hospital, aged 75, died, September 19, in Webster, of pneumonia

Fred Lewis Neely ♂ Shelton, Wash., Western University Faculty of Medicine, London, Ont., Canada, 1908, served in the Canadian Army during the World War, aged 50, died September 12, in Olympia, as a result of brain injuries received when he fell from a four story hotel window

Isadore Maurice Leavy ♂ Lynbrook, N Y, Long Island College Hospital, Brooklyn, 1911, served during the World War, on the staff of the Montefiore Hospital for Chronic Diseases New York, aged 46, died, October 7, in the Mount Sinai Hospital, New York, of pneumonia

John Brett Trainor, Fall River, Mass., McGill University Faculty of Medicine, Montreal, Que., Canada, 1897, member of the Massachusetts Medical Society, aged 67, on the staffs of the Union Hospital and St Anne's Hospital, where he died, September 20, of cerebral thrombosis

Isidor J Propper ♂ Gary, Ind., Cleveland College of Physicians and Surgeons, Medical Department Ohio Wesleyan University, 1900, aged 67, on the staffs of St Mary's Mercy Hospital and the Methodist Episcopal Hospital, where he died, September 27, of pneumonia

Frank Guy Devereux, Portland, Maine, College of Physicians and Surgeons, Medical Department of Columbia College New York 1880 member of the Maine Medical Association aged 76 died October 2, in the Maine General Hospital, of coronary occlusion

Lotharo L Morey, Vandalia Ill Physio Medical Institute Cincinnati, 1881 Physio-Medical College of Indiana, Indianapolis, 1882, member of the Illinois State Medical Society, aged 78, died September 14 of interstitial nephritis

Osmon Charles Church, Steeleville, Ill Barnes Medical College St Louis, 1910 member of the Illinois State Medical Society, served during the World War, aged 61 died, September 9, in the Christian Welfare Hospital, East St Louis

Joseph Pinkney Turner ♂ Greensboro, N C. University of Maryland School of Medicine, Baltimore, 1896 medical director of the Jefferson Standard Life Insurance Company, aged 63, died, September 29, of coronary thrombosis

Joseph Francis Fallon, Brookline, Mass., Jefferson Medical College of Philadelphia, 1908, member of the Massachusetts Medical Society, served during the World War, aged 53, died, October 14, of hemorrhage due to ruptured esophageal varices

J Fred Eckerson, Shelby, N Y., University of Buffalo School of Medicine, 1899, member of the Medical Society of the State of New York, aged 58, died, September 10, in Medina, of cerebral hemorrhage and hypertension

George Junkin Gouger, Concord, N C. (licensed in North Carolina in 1901), member of the Medical Society of the State of North Carolina, aged 73, died, September 12, of coronary thrombosis and pernicious anemia

Osmyn Baker, Penns Grove, N J. Columbian University Medical Department, Washington, D C., 1899, aged 68, died, October 11, in the Homeopathic Hospital, Wilmington, Del., of cerebral hemorrhage

William Frank Henderson, Blacksburg, Va., Washington University School of Medicine, Baltimore, 1876, member of the Medical Society of Virginia, aged 81, died, September 23, of chronic myocarditis

Auxilien Clement J Gervais, Milton, N Y., University of Vermont College of Medicine, Burlington, 1927, aged 34, died, September 20, in the Vassar Hospital, Poughkeepsie, of chronic nephritis

Arthur Densmore Spence, South Lebanon, Ohio, Miami Medical College, Cincinnati, 1895, member of the Ohio State Medical Association, aged 67, died, October 4, of arteriosclerosis

Alphonso A W Bley, Los Angeles, University of Pennsylvania Department of Medicine, Philadelphia, 1886, also a pharmacist, aged 83, died, September 29, of gastric ulcer

James Edward Poulin, Waterville, Maine, Medical School of Maine, Portland, 1905, on the staff of the Thayer Hospital, aged 55, died, October 2, of lobar pneumonia

Otto Elbert Harmon, Kiowa, Kan., Keokuk (Iowa) Medical College, College of Physicians and Surgeons, 1905, aged 61, died, September 17, of carcinoma of the jejunum

James Allan Todd, Toronto, Ont., Canada, University of Toronto Faculty of Medicine, 1879, L R C S, L R C P, Edinburgh, Scotland, 1880, aged 82, died, September 19

William Henry Bennett, Los Angeles, Tufts College Medical School, Boston, 1906, served during the World War, aged 65, died, September 4, of carcinoma of the stomach

Francis Emanuel McNamara, Milwaukee, Hahnemann Medical College and Hospital, Chicago, 1879, aged 79, died, September 17, of atrophic cirrhosis of the liver

Allison Herbert Edwards, Grand Rapids, Mich., Grand Rapids Medical College, 1900, city health officer, aged 53, died, September 29, of coronary occlusion

Otho Christian Buxton, Webster City, Iowa, King Eclectic Medical College, Des Moines, 1885, aged 78, died, September 17, of coronary thrombosis

William Stevenson, Des Moines, Iowa, Drake University Medical Department, Des Moines, 1894, aged 77, died, September 15, of pernicious anemia

William Myron Edgerton, Wichita, Kan., St Louis College of Physicians and Surgeons, 1899, aged 65, died, September 12, of cerebral hemorrhage

Frank Wilmoth Gray, Washington, D C., Howard University College of Medicine, Washington, 1925, aged 42, died, October 20, of bronchopneumonia

John M Campbell, Russellville, Ark., Memphis (Tenn.) Hospital Medical College, 1890, police judge, formerly mayor, aged 76, died, August 28

Edward Abeles, Leavenworth, Kan., Harvard University Medical School, Boston, 1878, aged 80, died, September 21, of cerebral hemorrhage

Cyrus B Phillips, Pitman, N J., University of Maryland School of Medicine, Baltimore, 1882, aged 76, died, September 16, of heart disease

Cyrus Maxwell Boger, Parkersburg, W Va., Hahnemann Medical College and Hospital of Philadelphia, 1888, aged 74, died, September 2

John H Dubbs, Philadelphia, University of Pennsylvania Department of Medicine, Philadelphia, 1891, aged 67, died, September 6

Edward Francis Lawlor, Lawrence, Mass., Baltimore Medical College, 1905, aged 57, died, October 6, of coronary sclerosis

Loring V Miner, Sublette, Kan. (licensed in Kansas in 1901), aged 75, died, September 30, in an automobile accident.

Correspondence

INJECTION METHOD FOR HERNIA

To the Editor—In the past four months a number of my patients who have had injections for sclerosing inguinal hernias have reported that they have been sexually impotent since the injections of the sclerosing fluid. One dated back to eight years, several to two years, and one was of four months.

I think the patient should be told of the possibility of sexual impotence following the use of these injections in all inguinal hernias

OSCAR A STRAUSS, M.D., Chicago.

THE TUBERCULIN REACTION

To the Editor—Dr Ustvedt's statement (*THE JOURNAL*, March 9, p 851) that "tuberculin negative individuals who are not exposed to infection cannot be expected to develop clinical tuberculosis" has been the crux of our argument, which Dr Harrington and I have emphasized in numerous publications for fifteen years. Therefore his statement that "this is a fact that has been neglected by many investigators and lately by Myers and Harrington" is hardly justified. On this point, we are in complete agreement with Ustvedt. One of the objects of our paper (*THE JOURNAL*, Nov 17, 1934, p 1530) was to emphasize the fact that children who react negatively to the tuberculin test, when observed over a period of years and into adult life, are much better risks from the standpoint of the development of clinical tuberculosis than children who at the same time have positive tuberculin reactions. To be sure, each of our negative reactors who later developed clinical tuberculosis first became a positive reactor, whereupon the tuberculosis status was essentially the same as in the group who originally reacted positively to the test, that is, in each instance they developed the benign first infection type of tuberculosis, which every one of our originally positive reactors had when our observations began. One of the main points of our paper was to emphasize the fact that apparently healthy children who react positively to the tuberculin test are not as well immunized as we formerly believed. Already 10 per cent of those whom we examined fourteen years ago have developed clinical forms of disease. Such a record in smallpox or diphtheria would dampen enthusiasm for immunization against these diseases.

Dr Ustvedt calls attention to the observations of Dr Heimbeck, which showed that all the student nurses who were negative to the tuberculin test on admission to the nursing school became positive tuberculin reactors by the time of graduation, and that, during the three years of training, 48 per cent of the girls who were positive to the tuberculin test when they entered training developed clinical tuberculosis before graduation, while 34.6 per cent who were originally negative developed clinical tuberculosis, "including milder forms of tuberculous disease, as erythema nodosum."

On analysis of Dr Heimbeck's figures, one is impressed with the large number of originally negative reactors grouped as having developed clinical disease, who had only erythema nodosum, enlargement of the hilus lymph nodes, and so on. If Dr Heimbeck's students develop the same types of lesions as did the students of nursing and medicine we have observed, many of those he describes with parenchymal lesions must have been due only to the first infection benign type of tuberculosis. We do not look on erythema nodosum, enlarged hilus lymph nodes, or even parenchymal lesions of the first infection type as clinical disease in the strict sense of the word. We have not yet seen one of these persons, either in childhood or in adult life, fall ill from the first infection type of focus per se. When symptoms do appear in this group, they are due in our experience to a manifest complication.

One must assume, therefore, that the 346 per cent of previously negative reactors who, according to Dr Heimbeck's classification developed clinical tuberculosis for the most part had lesions of the first infection type. If this should be carried to its logical conclusion all the girls who became positive to the tuberculin reaction had clinical disease, since all of them must have had lesions somewhere in the body in order to produce positive tuberculin reactions. The fact that the roentgen examination of the chest did not reveal enlargement of the lymph nodes or parenchymal lesions, and the fact that erythema nodosum did not occur, does not rule out lesions so small that the x-ray film would not reveal them in the lungs or hilus lymph nodes or in other parts of the body which do not lend themselves to roentgen examination. Moreover all the girls who entered the school of nursing with positive tuberculin reactions had first infection type of lesions somewhere in their bodies. If one had a complete history of each case and serial x-ray films, in all probability it would be found that they had already passed through the form of tuberculosis which has been seen to develop among the negative reactors when they became positive. Therefore, according to Heimbeck's classification, each of these girls who gave a history of having had erythema nodosum, or had an x-ray film showing at some previous time enlargement of the hilus nodes or even parenchymal involvement, would have to be classified as clinical cases of tuberculosis. The only difference in the two groups is that he saw the one group experience what the other group had experienced before they came under his observation.

In one of our groups of positive reactors, there was x-ray evidence of disease in approximately 22 per cent on first examination, such as pneumonic areas about first infection foci, deposits of calcium in the hilus, and Ghon tubercle formation in the lung parenchyma. If a very complete history were obtainable, in all probability there would be enough others who had had attacks of erythema nodosum and other mild manifestations of the first infection type of disease to increase our percentage to approximately that which Heimbeck observed in his previously negative group of nurses.

During the past fifteen years we have observed the complete evolution of tuberculosis in the bodies of a good many children and adults, that is, we have seen the tuberculin test first become positive and have watched the first infection type of disease develop and come under control without producing any significant symptoms. Later, in the same cases we have observed the reinfection, destructive type of disease make its appearance and progress to the advanced stage with serious illness and in some instances death. We have carefully observed persons negative to the tuberculin test, who later became positive. In the small percentage of this group who develop parenchymal lesions of the first infection type there is an interval of from several weeks to four or five months after the test becomes positive before the lesion is large enough to cast a shadow that can be visualized on the x-ray film. Although these persons are not ill there is an immediate and a remote danger. The immediate danger consists chiefly of bacilli from the first infection focus finding their way to a ramification of a bronchus, the pleura, the blood stream or the subarachnoid space. Tuberculous pneumonia in a very destructive form may follow the outpouring of bacilli in a bronchial ramification. When the lesions are located near the periphery of the lung pleurisy with effusion, which is a reinfection form of tuberculosis, is a rather common immediate danger. Again when the lesion, whether in the parenchyma or in the regional lymph nodes, burrows into a blood vessel, miliary tuberculosis often follows. This also is a reinfection form of disease. When a first infection focus is in or near the central nervous system and its bacilli are set free into one of the ventricles of the brain or directly into the subarachnoid space diffuse tuberculous meningitis usually results. Any one who watches a sufficiently large

group of negative reactors become positive will see some of these reinfection types of tuberculosis, which develop soon after the first infection type of focus is established. Wallgren (*J Pediat* 5 291 [Sept] 1934) has pointed out that these fatal forms of tuberculosis in infants occur most frequently within the first three months after infection develops. Dr Heimbeck has already reported a few such cases among student nurses.

The remote dangers develop long after the first infection focus is laid down and consist of chronic lesions which make their appearance in the lung, kidney, bones and joints. No one can observe a sufficiently large group of negative reactors a long time after they become positive to the tuberculin test without seeing some suffer from these remote dangers. In reality the groups Scheel, Ustvedt and Heimbeck have compared are not comparable unless they know the tuberculosis situation among the ranks from which their positive tuberculin reactors came. The only way a true comparison can be made is to observe the negative reactors who become positive over a period as long as their positive reactors have been positive.

We would be interested to know whether Dr Scheel, reporting on medical students, and Dr Ustvedt, reporting on 4,800 children, used the same classification as Dr Heimbeck with reference to clinical disease. In our group, only cases of frank pulmonary tuberculosis of the destructive reinfection type were included. Apparently, the chief point of misunderstanding lies in the different ways in which cases of tuberculosis are classified. If the same classification was used, we are apparently in very close agreement.

Dr Ustvedt mentions allergy in both his first and concluding paragraphs, and he shows a tendency to minimize its importance. He calls attention to a group of patients with erythema nodosum in which there was a high degree of allergy. In this group there was a morbidity of 103 per cent during the first year and for the following years up to the tenth from 3 to 0 per cent. We are cognizant of the fact that erythema nodosum is sometimes the result of a high degree of allergy to tuberculo-protein but by no means do we consider every case as due to this cause. For example, Pilot (*Central Society for Clinical Research*, October 1933, p 16) after making a careful study of this condition said "It would appear that erythema nodosum is not a clinical entity but a peculiar hypersensitive response of the skin to toxic products from foci of infection due to streptococci, tubercle bacilli, the virus of lymphogranuloma inguinale and perhaps other agents." Therefore there hardly seems justification for considering every case of erythema nodosum as due to tuberculosis, even though the tuberculin test is markedly positive. The South African studies (*Publications of the South African Institute for Medical Research* Johannesburg, vol 5, 1932, *Bull Internat Union Against Tuberculosis* 12 234 [July] 1935), which showed that the highly allergic individuals were far more likely to develop true clinical disease than others, are significant in this connection.

It seems paradoxical to look on allergy to pollens and foods as being a responsible factor for the development of hay fever, some forms of asthma, rhinitis and gastro-intestinal disturbance, and at the same time to look on allergy to tuberculo-protein not only as a factor without harm but one that is beneficial to the human body. There has been an abundance of experimental work to show that allergy is the cause of the much more intense reaction of the tissues to tubercle bacilli of reinfection than is seen in first infection. The harmful effect of allergy to tuberculo-protein is now recognized by such large numbers of workers that we are already looking forward to a method of desensitizing highly allergic individuals in order to prevent necrosis and great destruction of tissue from the reinfection type of disease.

J ARTHUR MYERS, M D, Minneapolis

Queries and Minor Notes

ANONYMOUS COMMUNICATIONS and queries on postal cards will not be noticed. Every letter must contain the writer's name and address but these will be omitted on request.

ANGINAL ATTACKS WITH GALLBLADDER INFECTION

To the Editor—Kindly discuss the following symptom complex, suggesting the diagnosis, prognosis and treatment including the diet. A man aged 59 single complains of repeated attacks of an anginal syndrome while walking characterized by a feeling of pressure or constriction behind the manubrium sterni which is relieved by coming to a stop or on sitting down. There is no pain associated with the discomfort no dyspnea a slight increase in the pulse rate and it does not radiate but remains fixed back of the sternum necessitating slowing up or sitting down. It passes away in from three to six minutes. He is extremely nervous owing to difficulties at his place of employment. He had insomnia which lasted throughout the latter eight months of 1934 but from which he is now fairly recovered. The chest discomfort first manifested itself during the first week of February 1935, and during March it appeared every second or third day with the same train of symptoms. During April the same thing happened seven times while in May and June it averaged about once weekly. On one occasion it followed a slight difference of opinion with a neighbor. In two or three other instances it manifested itself while he was slowly walking after partaking of a large meal on two of the latter occasions he appeared exhausted, with a somewhat irregular pulse which became regular in a very short time. The heart is not enlarged (the cardiac shadow is normal) and the radial pulse is full and regular, averaging from 60 to 78 throughout the twenty-four hours. It is negative as to murmurs. The blood pressure averages about 105 systolic 68 diastolic he has had low blood pressure for the last fifteen years. The cardiogram in April and June of this year as well as in 1933 was negative. Fluoroscopic examination on various occasions revealed an abundance of gas in the stomach with a pushing up of the left side of the diaphragm. There is a history of cholecystitis with possible stones beginning in 1918 (last colic which was never of the passing stone type, in 1929). The patient has been adhering to a strict low fat diet and relieving the colic with rectal enemas an ice bag and morphine. Many roentgenograms have been taken the last one about two years ago when the gallbladder was not visualized. The roentgenologist's report was pathologic gallbladder. From 1918 to 1929 the patient had about fifteen attacks of dull pain about the gallbladder and on five different occasions had attacks of syncope necessitating his removal to the hospital. The attacks of 1918, 1921 and 1925 came on without warning four or five hours after eating. When he recovered from these attacks gastric discomfort followed by vomiting relieved him completely, and he was able to return to his usual duties within twenty-four hours. The syncopal attacks of 1929 and 1933 were not followed by vomiting but as usual the patient was well in twenty-four hours during his last gallbladder colic in 1929 he was jaundiced for forty-eight hours, the skin and urine cleared up in the time mentioned. The latter happened again during the latter part of the same year. He is not a drinker never had syphilis has normal urine weighs (stripped) 163 pounds (74 kg.) is 66 inches (168 cm.) high and is the picture of health.

M D New York.

ANSWER—The association of myocardial disease and disorders of the gallbladder is a common one and the etiologic role of gallbladder disease in the production of myocardial disease has been recognized for many years. Whether this relationship obtains here can only be conjectured. In spite of negative electrocardiographic observations, frequently observed in cases of the type described, there is no question that this patient suffers from stenocardiac attacks on a myocardial basis. Anginal attacks and even coronary occlusion occur without pain, the only subjective disturbances noted by the patient being precordial pressure or severe dyspnea. Other signs elicited on examination are changes in the rate and rhythm of the pulse as already noted, and in some instances a drop in the systolic blood pressure during or immediately after an attack. Electrocardiographic evidences of myocardial disease may be found only after many years or never. Patients with severe biliary colic may faint if the pain is very intense. Rarely there may be a Stokes-Adams syndrome, but it is hardly possible that it has occurred in this case without some electrocardiographic evidence being found. It should not be difficult to offer advice for prevention of attacks, because the patient himself has noticed that overeating, exertion such as walking after eating, and emotional or gastro-intestinal upsets provoke attacks. Not infrequently cardiac attacks are associated with fullness and belching after eating, so that the condition is diagnosed as "indigestion" and the effect taken for the cause.

It is advisable for the patient to avoid overeating at any one particular meal particularly the many course big dinners, to avoid highly spiced foods and alcoholic beverages, to rest for at least an hour or more after each meal, and under all circumstances avoid undue exertion and emotional upsets. For immediate relief of the attacks glyceryl trinitrate tablets in

0.00065 Gm ($\frac{1}{100}$ grain) doses should be placed under the tongue. Relief is generally obtained after one or two tablets at intervals of two minutes. Some physicians object to the drug because of lowering blood pressure with the resultant diminishing coronary flow. This objection is more academic than real. One of the methylxanthine preparations, such as aminophylline, may be given three times daily for its tendency to promote coronary flow. A combination of 1 Gm. (15 grains) of sodium bromide in 75 cc (2 drachms) of rubarb and cod mixture after meals may relieve both the epigastric and the subjective cardiac distress.

Mackenzie's favorite drug for this was ammonium bromide in 1 Gm doses taken frequently enough to keep the patient free from subjective discomfort, later decreasing the dose. Finally the question of a cholecystectomy must be considered. Should the patient have a recurrence of colic especially of the obstructive biliary type, operation may be advisable as a curative measure for the calculous condition and prophylactic for the cardiac condition.

EPIPHYSEOLYSIS

To the Editor—In August 1934 a boy, aged 15 years fell from his horse. He got up and walked and continued doing his usual farm work, not considering that he was badly hurt. He now states that his only sign of injury was that his leg on the inside and front of the thigh turned black and blue. A month after the fall he began to limp slightly. His lameness gradually became worse. When he came to me in April 1935 he was walking with difficulty with the aid of a crutch. He complained of pain in his knee of pain at night after a strenuous day and of pain in his hip if he lay on the injured side at night. The boy was fat weighing 191 pounds (86 Kg.). His height was 65 inches (165 cm.). There is eversion of the foot on the injured right side and apparent shortening of the right leg of half an inch. Accurate measurement is difficult because of rolls of fat overlying the anterior superior spines. Flexion at the hip joint elicited pain. Roentgen examination discloses pathologic change in the head and neck of the femur, apparently a slipping of the epiphyseal end. The roentgenogram looks like an impacted fracture of the surgical neck of the femur but the clinical history does not line up well with such a diagnosis. I never have known a patient with fracture of the neck of the femur to walk for a month before going lame. Along with the foregoing I suspect endocrinism since at 15 years of age the external genitals are almost infantile in their lack of development. I should like to have suggestions as to diagnosis, prognosis and treatment. At this time I have had the patient in bed six weeks on a reduced diet using sand bags for supporting the leg in a comfortable position. He is now free from pain. Please omit name.

M D Kansas.

ANSWER—The history justifies a diagnosis of "slipping of the proximal femoral epiphysis" or as it has sometimes been called, "epiphyseolysis." This condition is not uncommon. Most of the patients are boys of from 13 to 15 years of age who are abnormally fat. The obesity is particularly marked about the hips, and the patients usually show retardation in sexual development. This picture is sometimes spoken of as Froelich's syndrome.

The theories regarding the etiology of the slipping of the capital epiphysis of the femur vary from one of a purely mechanical basis to that which attributes the condition to disturbances of the endocrine glands. The strain of weight bearing may be the only extrinsic factor to cause the epiphysis to begin to slip, but not infrequently a history can be obtained of minimal trauma such as a fall that causes no immediate symptom or disability. The condition is a progressive one and unless treatment is instituted the slipping usually continues, with some bending down of the neck of the femur until there is marked deformity and disability. Occasionally the capital epiphysis will become completely detached from the neck, remaining as a loose body in the hip joint.

Regardless of what type of treatment is used healing occurs only by the fusing of this epiphysis to the neck of the femur, thus arresting any further growth from the epiphyseal cartilage at this level. This causes little difference in leg length, since the condition itself is usually present after most of the longitudinal growth has been completed, and less than 10 per cent of the growth of the femur itself takes place from this epiphysis.

Treatment that has been most effective is complete immobilization in a plaster body and leg cast, which keeps the affected leg in a position of extreme abduction and internal rotation. The position is the same as that recommended by Whitman for fractures of the neck of the femur. Medical and dietary measures are indicated to attempt to reduce the weight, and beneficial results have been reported from the oral administration of desiccated thyroid.

The shortest period in which one can hope to obtain complete healing is from six to nine months. Roentgenograms should be taken of the opposite hip, since not uncommonly the condition is bilateral, and, if the patient is allowed to be ambulatory on

crutches with the hip that is most marked protected by a cast, slipping of the opposite capital epiphysis may occur

The diet, besides being low in fat, should contain more than the usual amount of vitamins and calcium. There is little evidence that the addition of the inorganic salts of calcium and phosphorus are of any therapeutic value

ERYSIPELAS

To the Editor—I have under my care a man aged 22 who for the past five years has had recurrent attacks of pain swelling and redness on the anterior surface of the legs. He states that the first attack was accompanied by a chill high fever vomiting and headaches. These attacks occur from every two to nine months. The skin lesion occurs on either of the legs but never on the two at the same time. The constitutional symptoms have become milder with each succeeding attack. The skin lesion is a red swollen area with elevated border and feels warm to the touch. A diagnosis of recurrent erysipelas was made and during his present attack he was given 10 cc. of erysipelas antitoxin from which he suffered an allergic reaction a week following the injection. At present I am using ultraviolet irradiation and Parke Davis & Co's Erysipelas Streptococcus Immunogen. Will you please make suggestions for further treatment? Please omit name. MD Texas

ANSWER—Erysipelas is recognized as more than a local disease. There is a general lowered resistance to the streptococcus producing such symptoms. The use of streptococcus toxin and vaccine together in producing active immunization offers the most effective method of prevention of recurrent attacks of the disease. The streptococcus if possible should be obtained from the skin of the patient.

Birkhaug (Nelson Loose Leaf Medicine 1 4490) advised injections intramuscularly every seven to ten days with gradually increasing dosages for seven to eight weeks from a mixture of about 1,000 skin test doses of toxin and 2,000,000 killed streptococci to about 200,000 skin test doses of toxin and 100,000,000 killed streptococci. The majority are protected for two years. The persistence of immunity is determined by intradermal injections of from seven to ten skin test doses of toxin and about 10,000 killed erysipelas streptococci. If there is a red areola larger than 1 cm., the active immunization should be repeated. The test may be repeated every three months if desired.

Nonspecific protein therapy has been of value in raising the immunity, especially in the treatment of erysipelas. However the antitoxin has been reported on most favorably with a lowered morbidity and mortality in the treatment, but no permanent immunity is given and it is not indicated in preventive treatment (Symmers, Douglas, and Lewis, K. M. The Antitoxin Treatment of Erysipelas, THE JOURNAL Sept 24 1932 p 1082).

Fantus briefly reviewed the general treatment in THE JOURNAL, July 21, 1934. The young, the aged and debilitated individuals have a much lowered resistance to the disease. General measures are particularly important in these cases.

DERMATOMYOSITIS

To the Editor—I have a daughter aged 24 who has been bedfast for five months with what has been diagnosed by able men in San Francisco as dermatomyositis. As I am unable to find anything in my textbooks or in current medical literature to which I have access and as I have not been able to find out much about this trouble from the doctors I have consulted, I am asking you to cite references to me or assist me in any way that you feel that you can in ascertaining the latest and best medical light on this subject. Needless to say I am greatly concerned as to the outcome of the case and practically in the dark as to the cause and rational therapy. MD California

ANSWER—Dermatomyositis was described years ago and was given its name by Unverricht in 1891. It is an acute or chronic disease characterized by an insidious onset with vague symptoms such as malaise, anorexia and pain in the back and extremities. These are followed more or less promptly by local edema with an inflammation and degeneration of the muscles and with some form of dermatitis, eczematoid, erysipeloid, urticarial, scleroderma-like, or nodular, such as erythema multiforme or erythema nodosum. Its usual location is on the extremities.

The edema may be soft or hard and is followed by atrophy, sometimes by pigmentation. The disease is supposedly infectious often preceded by infection of the upper respiratory tract. *Bacillus coli*, staphylococci, streptococci or meningococci have been found in the muscles in various cases.

The prognosis is grave. Fifty per cent of the patients die. The acute cases last only one or two weeks, the chronic ones may last as long as two and one half years. Remissions are common, not seldom being followed by exacerbations. When

recovery occurs more or less atrophy must be expected and measures to prevent contractures should be taken early in the course of the chronic cases.

The treatment consists of rest in bed with a good diet, care of the emunctories and of the skin, but without massage.

J. C. McGarrahan (Dermatomyositis, THE JOURNAL, March 3 1934, p 680) made cultures from the nose and tested vaccines made from them by endermic injection. Only those made from the staphylococcus gave a positive skin reaction. The use of a mixture of three staphylococcus vaccines gave prompt improvement.

McGarrahan's case was peculiar in its eosinophilia, as high at one time as 29 per cent. Four weeks after the beginning of treatment with vaccine, it had reduced to 5 per cent and there was a corresponding clinical improvement. The high eosinophilia increased the difficulty of differentiation between dermatomyositis and trichinosis, the disease that most closely resembles it clinically. The history of eating raw pork, the stormy onset not uncommon in trichinosis, and the discovery of embryo trichinae in bits of muscle from near the attachment of a tendon should clear the diagnosis. Removal of infected teeth in McGarrahan's case had little effect. For local treatment he used dry hot flannel bandages with additional baking of the affected parts for a half hour at a time, three times daily.

W. G. Brock (Dermatomyositis and Diffuse Scleroderma, Arch. Dermat. & Syph. 30 227 [Aug.] 1934) tried aminoacetic acid without effect. If desired, it can be given in doses of from 0.6 to 2.0 Gm daily, divided into two or three doses. Brock got the greatest benefit from intravenous injections of typhoid vaccine.

Short accounts of the disease are to be found in Pusey's Dermatology, fourth edition, New York, D. Appleton & Co., 1924; in Sutton's Diseases of the Skin, ninth edition, St. Louis, C. V. Mosby Company 1935; and in Ormsby's Diseases of the Skin, fourth edition, Philadelphia, Lea and Febiger, 1934. All these give references to articles in the literature.

Another recent article is the one by J. T. Ingram and M. J. Stewart (Brit. J. Dermat. & Syph. 46 53 [Feb.] 1934).

DISORDERS OF MENSTRUATION

To the Editor—I have a patient aged 13 years who has had excessive menstruation for about a year. The family history and personal history are negative except that the mother has always menstruated more than normal. About two years ago the patient began to have marked development of secondary sexual characteristics. About a year ago she stumbled while running and since has had excessive flow to the extent of becoming very anemic and not able to be about during her menses. During the last few months she has had vomiting on the first day with much pain following and an excessive flow. On examination the patient is normal otherwise with first degree backward tipping of the uterus and some anemia. She has taken the usual medication and ovarian preparations without any benefit. Please advise as to treatment and probable pathologic condition. Please omit my name and address. MD, Kansas

ANSWER—This is most likely a case of functional uterine bleeding associated with hyperplasia of the endometrium. The condition is now believed to be due to a hypophyseal disturbance. The way to prove the diagnosis of hyperplasia is to perform a curettage. For this purpose the cervix need not be dilated much and only a small amount of material need be curetted out of the uterine canal. Any pathologist can readily make the diagnosis from curetted material. The curettage will also help to rule out any other possible cause of bleeding, such as an intra-uterine polyp.

Functional bleeding may occur at any time in the menstrual cycle but chiefly at the beginning and at the end of the reproductive career when it is spoken of as the 'hemorrhage of puberty and climacteric' or 'menopausal hemorrhage' respectively. The large majority of cases are observed at the time of the menopause.

Ovarian preparations will most likely be of little avail in the treatment of this condition. In most cases of functional bleeding there is not only hyperplasia of the endometrium but also absence of functioning corpora lutea in the ovaries. The changes in the endometrium are the result of an excessive proliferation due to stimulation by an abnormal amount of estrogenic substance. To overcome this condition Novak has recommended the use of anterior pituitary-like gonadotropic extract from the urine of pregnant women. He and others have reported encouraging results with this substance. In women at or near the menopause, one may resort to radiation therapy or to hysterectomy. In a young girl, however, efforts must be made to build up the patient's general resistance, food and drugs should

be prescribed to combat the anemia, and the so-called anterior pituitary-like extract should be administered hypodermically. Occasionally there are spontaneous cures of functional bleeding, especially in young girls.

PILONIDAL SINUS

To the Editor—Will you kindly inform me how to judge the extent of the incision for complete eradication of a pilonidal sinus also land marks injection of dyes and so on? Also please refer me to literature on the subject

SIMON ENGLANDER, M.D. Cleveland

ANSWER—The extent of the incision may best be judged by injecting the sinus with iodized poppyseed oil and taking a roentgenogram to determine the extent of the tract. Frequently the secondary tracts extend quite far laterally, especially secondary to infection in the primary tract. A portion of the cyst wall or the sinus tract may extend into the sacrococcygeal joint or into the hiatus of the sacrum. It frequently is in close relation to the periosteum over the coccygeal segments.

At the time of the operation, the sinus or cyst is evacuated by aspiration or pressure over the sacrum. The point of the syringe is inserted into an orifice and a purse string suture tied round it. Some dye such as methylene blue or indigo carmine is injected and followed by gentle massage of the region.

A small tongue of skin over the region is excised, but the subcutaneous tissues must be widely excised underneath both sides and extending down to the periosteum and where the rudimentary sac enters or ends at the sacral hiatus. If the fascia over the sacrum and the coccyx is stained with the dye it should be removed.

Excision before infection develops is the preferable treatment, as this often produces wide tracts, which prevent good healing.

Three methods of treatment of the wound have been used after excision of the sinuses. These are packing it wide open, partial closure and complete closure. If there is recent or persistent infection, the wound should be left wide open and packed with petrolatum gauze. Some advocate leaving a small drain after obliterating all dead spaces and controlling hemorrhage carefully, while others state that no drains should ever be left. If a drain is inserted it should be at the upper angle of the wound, as it is farther from the anus and there is less danger of infection.

If primary closure is done, a flap is swung over from one side to close the defect. The flap is anchored to the fascia over the sacrum and closed carefully in layers. The lateral incision is closed transversely for about a third of the distance.

UREA TEST IN URINALYSIS

To the Editor—Kindly give me your opinion as to the advisability of including the qualitative and quantitative urea test in a twenty-four hour urine specimen. Is it considered necessary in the ordinary routine examination of patients to include this with the microscopic and the other chemical tests?

J. W. HOPKINS, M.D. Glendale, Calif.

ANSWER—In itself the estimation of urea in the urine is not of much diagnostic value, because its concentration is increased when much food is taken and diminished by a low protein diet. Liver diseases lessen its formation. Advanced renal disease lessens its excretion.

Urea is the chief organic constituent of the urine and its most important nitrogen waste product. Urea represents from 80 to 90 per cent of the total nitrogen of the urine. The amount of urea excreted varies under normal conditions between 20 and 40 grams in twenty-four hours. As urea is the most abundant solid of urine, it influences the specific gravity most. The specific gravity runs quite parallel to the amount of urea. The last two figures of the specific gravity give a fair estimate of the urea content provided there is no sugar and the chlorides are normal. 1020 conforms with the presence of 2 per cent of urea. 1016 with 16 per cent, and so on. When a twenty-four hour specimen is obtainable, the urea should be determined by the best and simplest clinically available method, the hypobromite method. For all clinical purposes the hypobromite method introduced by Knop, with the Doremus ureometer, is

sufficient. For accurate scientific work more elaborate methods are necessary, of which that of Mörner and Sjöqvist gives the most accurate results. Another method is that of Van Slyke and Cullen, which consists in treating the urine sample with urease, aerating the ammonia formed into fiftieth normal acid and titrating back the excess acid.

The quantitative urea test performed by the hypobromite method is so simple that it may well be included in the routine examination of twenty-four specimens of urine.

DELAYED HEALING OF BRUISE

To the Editor—I have a woman patient who severely bruised her leg three months ago. The area was black and blue for about a month and then gradually cleared up. At present the calf is very much enlarged and firm and painful. Roentgen examination shows a mottled appearance of the muscle of the calf and a somewhat moth-eaten appearance of the edge of the tibia. I have not encountered a condition like this before. Will you please advise me concerning this and what the treatment should be? Please do not publish my name.

M.D. Illinois

ANSWER—One is often surprised at how long it takes for a subcutaneous and subfascial extravasation of blood and serum to be absorbed and for the induration of the infiltrated tissues to disappear. This is particularly true if the part involved is in a lower extremity below the knee, where the constantly dependent position permits the action of gravity constantly to retard the return flow of blood.

It is not uncommon for the bones of the leg to show a "moth-eaten" appearance if the patient is beyond middle age and especially if varicosities of the veins are present. Such an appearance, however, does suggest the importance of making a Wassermann test and ruling out the presence of a syphilitic infection.

In the absence of a specific infection or a focus of low grade infection in the teeth or tonsils that could produce a metastatic inflammatory process at the site of injury, the treatment indicated would be rest, elevation of the limb for a part of each day, use of an elastic pressure bandage when the patient is up and about, and the use of warm applications for from half an hour to an hour twice daily while the leg is elevated, so as to stimulate circulation and favor acceleration of the venous return. The treatment that by all means should be avoided is any type of open operation with the associated risk of adding trauma and infection from the outside.

POSSIBLE USE OF OPTOCHIN IN URETER

To the Editor—In a case in my family there is a chronic inflammation of the lower third of the left ureter almost entirely extraluminal, following infection of the maxillary sinuses with streptococci and pneumococci. Both sinuses were opened the granulation tissue was cleaned out, and the results were excellent. But the infection of the ureter followed, possibly through lymph channels opened at operation. Now the streptococci are all gone formerly being present in long chains and only pneumococci are obtained by urethral catheter or the bladder urine. Since infection of the eye yields promptly to optochin, 1 per cent solution would it be safe to irrigate the ureter with the same or a little weaker? Has such internal use of optochin been made? What else would you advise? Certain medicinal dyes by mouth and mercurochrome locally partly control but do not destroy the pneumococci they return after a brief interval and the exudate from the presumably shallow ulcer pus and fibrin, block the ureter and cause severe colic.

M.D., Texas

ANSWER—We have not heard of optochin being used locally in the ureter. What evidence is there that there is a localized infection of the ureter? This is most unusual. If a definite narrowing has been demonstrated at this point by ureteral pyelography, dilation should correct the trouble. It is difficult to believe that any local application of an antiseptic could be of much benefit.

TREATMENT OF SYPHILIS

To the Editor—A man in the early sixties was found to have a positive Wassermann reaction as a result of a routine test. Physical examination is quite negative save for a sluggish pupil. He cannot remember the time of infection but believes that it was many years ago. How vigorous a course of antisyphilitic therapy should such a man be exposed to? Could you outline a safe regimen?

M.D., New York

ANSWER—The question of just how intensive treatment should be for this patient is dependent on the status of his syphilis. The sluggish pupil suggests the possibility of neurosyphilis, the which possibility could be determined by an examination of the spinal fluid. In a man aged 60 or more such an examination is not always advisable, but if his physical condition is otherwise good or if he is young for his years there can be no serious objection to an examination of the spinal fluid. The report of

this test would be a potent factor in determining subsequent treatment. Examination of the cardiovascular system should likewise be made to make certain that the patient does not have a syphilitic aortitis. If the spinal fluid and cardiovascular examinations are negative and there are no other signs of syphilis, little if any treatment is necessary in a person aged 60 or more in whom the infection is of many years' duration. In such a patient occasionally the use of mercury and small doses of potassium iodide by mouth is ample. If the spinal fluid examination is positive, however, treatment with arsphenamine and a bismuth preparation should be given. The dose of arsphenamine should be small, 0.5 Gm. of neoarsphenamine being the maximum dose. Following the first course of arsphenamine and the bismuth compound, subsequent treatment should be directed toward symptomatic relief. Further serologic reexaminations both of the blood and of the spinal fluid, should be dependent entirely on the patient's response to treatment.

IMPROVEMENT IN DIABETES UNDER DIGITALIS

To the Editor—A woman, aged 55 has had diabetes for twelve years and requires 24 units of insulin daily with a careful diet. Following large doses of tincture of digitalis which were begun in February the urine became sugar free. This was first noticed by the patient's husband early in March. The patient is now eating normally without restriction of carbohydrates. The urine without insulin and with daily examinations continues to remain sugar free. Have you any record of similar cases so responding to digitalis?

J T STEELE M.D., Dunsmuir Calif

ANSWER—We know of no similar case that has responded to digitalis in the manner described. Nor do we know of any reasonable explanation for what occurred unless the doses of digitalis were so large as to impair hepatic function.

It must be kept in mind that the improvement of the diabetes may be consequent to the heart failure, which presumably occasioned the administration of the digitalis, rather than to the drug itself. Cases have been reported in which diabetes has improved or disappeared as a coincident liver cirrhosis progressed. It is possible that in this case the period of passive hyperemia of the liver caused by the heart failure was enough to aggravate a previously existent mild hepatic cirrhosis.

If this explanation is correct (and it is only a guess at an otherwise inexplicable phenomenon), the improvement in the diabetes indicates a poor prognosis rather than an improvement. Undue sensitivity to insulin or the future occurrence of hypoglycemic attacks would corroborate this interpretation.

SHORTEST PROCESS OF LABOR

To the Editor—According to statistics what is the shortest time that it has taken a primipara at full term to go through the three stages of labor, all conditions normal, giving birth to a live and normal baby? Please omit name.

M D Arizona

ANSWER—Statistics regarding the length of labor are not reliable, because it is hard to determine when labor actually begins. Numerous cases are on record in which the baby was born within an hour after the first suggestion of pains, but it is more than probable that what the French call "insensible labor" had been going on for some time previously. Precipitate labors occasionally with fatal results, have taken place within an hour and several cases have had to be the subject of legal investigation to eliminate the suspicion of foul play. The shortest labor on record at the Chicago Lying-in Hospital was one hour and ten minutes for the three stages. The patient was a primipara 41 years of age, but in all probability she had had preparatory pains and considerable dilatation before she became aware that labor had begun.

BLOOD CHOLESTEROL AND METABOLISM

To the Editor—I would greatly appreciate information on the value and interpretation of blood cholesterol values. A version given me is that it can be used as an indication of metabolism as basal metabolism is.

L. EDWARD GIOVINE M.D. Flushing N.Y.

ANSWER—The normal limits of blood cholesterol may be considered to be between 120 and 200 mg. per hundred cubic centimeters. There may be wide and rapid fluctuations even during fasting. The intake of large quantities of butter eggs and meat for several weeks increases the blood cholesterol. There is an increase of blood cholesterol in about 50 per cent of pregnant women in the latter half of pregnancy. Low values occur in hyperthyroidism, fevers, anemias, cachexias and uremia.

High values are found in chronic nephrosis and acute nephritis. The highest values occur in pure nephrosis. There is often

an increase in the early stages of malignant growths. Biliary obstruction causes an increase unless there is a marked infection or cachexia. In myxedema and hypothyroidism the blood cholesterol varies from 250 to 750 mg. per hundred cubic centimeters of blood and is of value in diagnosis. There is an increase in diabetes mellitus with a faulty fat metabolism. A persistently high value indicates a bad prognosis. According to Rabinowitch the cholesterol is a more consistent guide to the patient's condition than the blood sugar. In lipemia of diabetes the cholesterol may be four times the normal. Insulin and dextrose cause a rapid reduction. A high blood cholesterol occurs in fasting when the body mobilizes its fat reserves for fuel. The reticulo-endothelial system plays an important part in cholesterol metabolism.

FIBRO ADENOMA OF BREAST IN A GIRL

To the Editor—A girl aged 10 years had a small tumor in the right breast about the size of a walnut. This was removed and a section showed it to be an adenofibroma which contained some dilated ducts. Several months later a mass developed in the left breast which is similar to the one that was in the right breast. This has gradually increased until it is about the size of a chicken egg. Should this tumor be removed or if not what treatment should she have? The breasts are undeveloped. Please omit name.

M D, Michigan

ANSWER—Five per cent of all benign fibro-adenomas of the breast are found under the age of 15 or before the onset of menstruation. Sixteen per cent of these benign tumors are multiple and of these multiple tumors one third occur bilaterally with or without an interval of time intervening between the appearance of the tumors. No immediate operation is indicated because of the bilaterality and multiplicity of these tumors. There is no reliable method for their cure except surgery, but in this instance the expectant treatment might be used, normal breast development being awaited before further surgery is attempted. There is no danger of malignant change at this age, although doubling or tripling the size of the tumor in a short period would justify its removal. The endocrine balance in this patient should right itself when menstruation is established and the object should be to delay treatment until then.

PAGET'S DISEASE

To the Editor—I have a patient who has been carrying a slight daily fever of a degree or two. The pulse ranges from 88 to 96. Pains and aches occur in the upper part of the body (chest area posteriorly and anteriorly). Some loss of weight has occurred. The spine over the cervical area is bent forward somewhat. When the patient walks he walks wide and flat footed to a degree rather marked. The blood shows 3,200,000 red blood cells and 56 per cent hemoglobin. The urine is normal. Paget's disease of the bone was found in the pelvis on roentgen examination. Will you tell me the best line of treatment to pursue? Please omit name.

M D Rhode Island

ANSWER—There is no specific medical treatment, and parathyroidectomy is not indicated in Paget's disease. The best that can be done is to treat the symptoms and to make sure that such treatment does not do harm.

SUTURE DEVICES IN TONSILLECTOMY

To the Editor—Is there an instrument on the market which mechanically and simply sutures bleeding points in the tonsillar fossae following tonsillectomy? May I have any information that you have on the subject?

DAVID MEZZ, M.D. Brooklyn

ANSWER—There are a number of instruments which mechanically and more or less simply carry a suture through the tissues of the tonsillar fossa and beneath the bleeding point. Having carried the catgut strand through by means of the instrument, the operator must then tie the suture himself. Any of the large surgical houses will supply information as to the names, and manner of use of instruments of this character.

OSMOTHERAPY

To the Editor—Hypertonic dextrose in 50 per cent solution has been prescribed in 20 cc. doses twice weekly for repeated intravenous use in scalp and skin infections. Is there not an appreciable element of danger in producing occlusion of the veins and a thrombus? What is the theory of this treatment?

M D Michigan

ANSWER—There is danger of damage to the veins which can be minimized by very slow injection. This is a form of "osmotherapy" depending for its effect on the upsetting of the delicate osmotic and colloidal balance of the blood and tissue fluids, which may result in an alteration of metabolic processes and a possible stimulation of resistance and repair.

Medical Examinations and Licensure

COMING EXAMINATIONS

AMERICAN BOARD OF DERMATOLOGY AND SYPHILOLOGY Written examination for Group B applicants will be held in various cities throughout the country March 14. Oral examination for Group A and B applicants will be held in Kansas City Mo. May 11-12. Applications for written examination should be filed with the secretary before Jan. 15. Sec. Dr. C. Guy Lane, 416 Marlboro St., Boston.

AMERICAN BOARD OF OBSTETRICS AND GYNECOLOGY Written examination and review of case histories of Group B applicants will be held in various cities of the United States and Canada, Dec. 7. Sec. Dr. Paul Titus, 1015 Highland Bldg., Pittsburgh (6).

AMERICAN BOARD OF ORTHOPAEDIC SURGERY St. Louis Jan. 11. Sec. Dr. Fremont A. Chandler, 180 N. Michigan Ave., Chicago.

AMERICAN BOARD OF OTOLARYNGOLOGY Kansas City, Mo., May 9. Sec. Dr. W. P. Wherry, 1500 Medical Arts Bldg., Omaha.

AMERICAN BOARD OF PSYCHIATRY AND NEUROLOGY New York Dec. 30. Sec. Dr. Walter Freeman, 1726 Eye St., N. W. Washington D. C.

AMERICAN BOARD OF RADIOLOGY Detroit, Dec. 12. Sec. Dr. Byrl R. Kirklint, Mayo Clinic, Rochester, Minn.

ARIZONA Basic Science Tucson Dec. 17. Sec. Dr. Robert L. Nugent, Science Hall, University of Arizona, Tucson.

CALIFORNIA Reciprocity Los Angeles Dec. 4. Sec. Dr. Charles B. Pinkham, 420 State Office Bldg., Sacramento.

COLORADO Denver Jan. 7. Sec. Dr. Harvey W. Snyder, 422 State Office Bldg., Denver.

CONNECTICUT Endorsement Hartford Nov. 26. Sec. Dr. Thomas P. Murdock, 147 W. Main St., Meriden.

KANSAS Topeka, Dec. 10-11. Sec. Board of Medical Registration and Examination, Dr. C. H. Ewing, 609 Broadway, Larned.

KENTUCKY Louisville Dec. 3. Sec. Department of Health, Dr. A. T. McCormack, 532 W. Main St., Louisville.

MARYLAND Medical (Regular) Baltimore, Dec. 10-13. Sec. Dr. John T. O'Mara, 1211 Cathedral St., Baltimore. *Medical (Homoeopathic)* Baltimore Dec. 10-11. Sec. Dr. John A. Evans, 612 W. 40th St., Baltimore.

MINNESOTA Basic Science Minneapolis Jan. 7-8. Sec. Dr. J. C. McKinley, 126 Millard Hall, University of Minnesota, Minneapolis.

NEBRASKA Basic Science Omaha Jan. 7-8. Dir. Bureau of Examining Boards, Mrs. Clark Perkins, State House, Lincoln.

NORTH CAROLINA Endorsement Raleigh, Dec. 9. Sec. Dr. Ben J. Lawrence, 503 Professional Bldg., Raleigh.

NORTH DAKOTA Grand Forks Jan. 7-10. Sec. Dr. G. M. Williamson, 4% S. 3d St., Grand Forks.

OHIO Columbus Dec. 3-5. Sec. State Medical Board, Dr. H. M. Platter, 21 W. Broad St., Columbus.

OKLAHOMA Oklahoma City Dec. 11. Sec. Dr. James D. Osborn Jr., Frederick.

TENNESSEE Memphis Dec. 18-19. Sec. Dr. H. W. Qualls, 130 Madison Ave., Memphis.

UTAH Salt Lake City, Dec. 10-12. Dir. Department of Registration, Mr. S. W. Golding, 326 State Capitol Bldg., Salt Lake City.

VIRGINIA Richmond, Dec. 11-13. Sec. Dr. J. W. Preston, 28% Franklin Rd., Roanoke.

WISCONSIN Basic Science Milwaukee Dec. 21. Sec. Prof. Robert N. Bauer, 3414 W. Wisconsin Ave., Milwaukee. *Medical* Madison Jan. 7-10. Sec. Dr. Robert E. Flynn, 410 Main St., LaCrosse.

Pennsylvania July Examination

Mr. W. M. Denison, director, Bureau of Professional Licensing, reports the examination held by the Pennsylvania State Board of Medical Education and Licensure at Philadelphia and Pittsburgh, July 9-11, 1935. Four hundred and twenty-four candidates were examined, of whom 418 passed and 6 failed. The following schools were represented:

| School | PASSED | Year Grad. | Number Passed |
|--|------------|------------|---------------|
| Yale University School of Medicine | (1933) | 1 | 1 |
| George Washington Univ. School of Med. | (1933) | 1 | 1 |
| Georgetown University School of Medicine | (1934, 23) | 23 | 23 |
| Howard University College of Medicine | (1934, 3) | 3 | 3 |
| Emory University School of Medicine | (1932) | 1 | 1 |
| University of Georgia School of Medicine | (1934) | 1 | 1 |
| Loyola University School of Medicine | (1935) | 1 | 1 |
| University of Louisville School of Medicine | (1933) | 1 | 1 |
| Lulane Univ. of Louisiana School of Medicine | (1933) | 2 | 2 |
| Johns Hopkins University School of Medicine | (1932) | 2 | 2 |
| University of Maryland School of Medicine and College of Physicians and Surgeons | (1934, 7) | 7 | 7 |
| Boston University School of Medicine | (1931) | 1 | 1 |
| Harvard University Medical School | (1933) | 1 | 1 |
| University of Michigan Medical School | (1934) | 1 | 1 |
| St. Louis Univ. School of Medicine (1911) | (1932, 8) | 10 | 10 |
| University of Nebraska College of Medicine | (1934) | 1 | 1 |
| Cornell University Medical College | (1934) | 1 | 1 |
| University of Buffalo School of Medicine | (1920) | 1 | 1 |
| University of Rochester School of Medicine | (1933) | 2 | 2 |

South Dakota July Examination

Dr Park B Jenkins, director, Division of Medical Licensure, reports the written and practical examination held by the South Dakota State Board of Health and Medical Examiners at Rapid City, July 16-17, 1935. The examination covered 14 subjects and included 115 questions. An average of 75 per cent was required to pass. Fourteen candidates were examined, all of whom passed. Three physicians were licensed by reciprocity and 1 physician was licensed by endorsement. The following schools were represented:

| School | PASSED | Year | |
|---|-------------------------|-----------|-------------|
| | | Grad | Per Cent |
| Rush Medical College | | (1934) | 85 86 |
| University of Louisville School of Medicine | | (1934) | 86 |

Book Notices

Diseases of the Chest By J Arthur Myers M.D. Professor of Medicine University of Minnesota Medical School. National Medical Monographs. Edited by Morris Fishbein M.D. Cloth Price \$3. Pp 385 with 62 illustrations. New York: National Medical Book Company Inc. Doubleday Doran & Co, Inc. 1935.

The writer in his preface states that our knowledge of diseases of the chest has increased so materially during the last ten years that much of what was written on the subject a decade ago is already obsolete. This increased knowledge has revolutionized methods of diagnosis, treatment and prevention. The x-ray film, the bronchoscope and the microscope are today the indispensable armamentarium of every physician who wishes to make a correct diagnosis of a pulmonary disease. The film locates and outlines the extent of disease, the bronchoscope visualizes a lesion and makes it possible to remove foreign bodies, secretions or tissue for biopsy, and the microscope is the "court of last appeal" in revealing the etiology of the condition. However, a careful history and physical examination are still the fundamental basis for the physician's diagnosis of disease.

The book discusses the first infection type of tuberculosis followed by a discussion of the tuberculin test in diagnosis. The percentage of positive reactors is steadily decreasing, until at present only about 30 per cent of college students and 15 per cent of high school students react positively. Then comes discussion of the roentgen examination in the diagnosis of tuberculosis of the first infection type. Myers advises periodic x-ray films of the chests of all children reacting positively to the tuberculin test. Chapter 4 deals with the examination and classification of tuberculosis of the first infection type. A history of exposure or the presence of an erythema nodosum is of great significance. On physical examination there is often no evidence of disease. Sputum is usually not obtainable, but a swab of the larynx and pharynx or the stomach contents may reveal tubercle bacilli. A classification is given for cases of this type. Chapter 5 discusses the treatment, prognosis and prevention of the first infection type.

Part II begins with chapter 6, on reinfection foci, endogenous and exogenous. Then follows a chapter on the acute forms of reinfection tuberculosis, such as miliary tuberculosis, meningitis, pneumonia and pleurisy. In chapter 8 the chronic reinfection types of pulmonary tuberculosis are considered. They are classified into minimal, moderately advanced and far advanced lesions. The next chapter discusses treatment. Chapter 10 is an excellent discussion of pneumothorax, giving the technic indications and results with some fair roentgenograms. Chapter 11 treats the subject of surgery of the chest wall and chapter 12 the interruption of the phrenic nerve. The last chapter on tuberculosis discusses the magnitude of the problem today.

Part III contains chapter 14, on nontuberculous diseases of the chest, and begins with the subject of pneumonia. Thirty pages are devoted to lobar pneumonia and bronchopneumonia. The next chapter is devoted to suppurative conditions of the bronchi, lungs and pleura. Chapter 16 considers tumors within the thorax. It is to be regretted that only nine pages are devoted to primary carcinoma of the lung, and only six lines to the physical observations in this disease, which today ranks second only to gastro-intestinal malignancy in frequency. A few lines are devoted to sarcoma, endothelioma and mediastinal growths. Chapter 17 discusses massive collapse, foreign bodies, spontaneous pneumothorax and embolism. Chapter 18 presents seven pages on pulmonary diseases due to moldlike bacteria, molds and yeastlike fungi. The next chapter describes diseases caused by inhalation of dust, such as hay fever, bronchial asthma and pneumoconiosis. There is an excellent chapter on silicosis.

Each chapter is followed by a brief list of references for those who desire more detailed information. There is an alphabetical index of twenty pages. For the medical student and the practicing physician, this book has presented the status of our present knowledge of the more important chest diseases.

International Narcotics Control By L E S Eisenlohr. Cloth Price \$4. Pp 295. London: George Allen & Unwin Ltd. 1934.

According to its preface, 'this book is concerned with dangerous drugs solely as a subject of international administration.' A great deal of work has obviously been devoted to the preparation of the book, but it is unfortunate that not more attention was given to accuracy and that the subject was not presented in complete and well balanced form. The book is highly theoretical and frequently inaccurate. By its omissions it produces a poorly balanced and somewhat distorted view of the situation. Its sophomoric pronouncements will not impress those familiar with the problem.

The discussion overemphasizes opium and the opium derivatives, pays little attention to the coca leaf and cocaine, and hardly mentions cannabis, although all these three classes of dangerous drugs have been the subject of international control, to the further strengthening of which increasing study is now being given throughout the world. Opium production in India and the Near East receives extended treatment. The situation in China, which produces about 90 per cent of the world total, receives scant attention.

Under the book's title of international control the author makes the statement that international control does not exist and proceeds, with airy disregard of actualities, to argue in support of a vague and impracticable proposal to supply the needs of the entire world for narcotic drugs from a single international factory under control of and operated by the League of Nations, to draw its raw material from three or four poppy farms nothing being said as to the coca leaf supply.

The book is confined almost entirely to the activities of the League of Nations and of the Permanent Central Opium Board in the field of narcotic control, treats the Supervisory Body, which is entirely independent and the most powerful organ functioning in international narcotic administration, as a sort of minor committee of the Permanent Central Opium Board and shows an almost total ignorance of the extensive practical and direct collaboration in these matters that has existed entirely outside the league for many years and has accomplished as much if not more than has the league. The collaboration of the United States and other nations not members of the league, without which no progress could have been made, is barely mentioned. In fact, the book gives the United States little or no credit for its work toward international cooperation to suppress the abuse of narcotic drugs and entirely omits mention of the consistent American effort to keep to the fore the question of limitation of the production of raw materials. The few references to the United States are inaccurate and misleading.

Although police preventive work is one of the most important factors in the international control of narcotic drugs the author plainly knows little of the organization of international police work in this field and has apparently based wide speculation on a few published league documents. Fault is found with the Opium Advisory Committee for not handling police work, and the author presents with apparent seriousness the naive idea

that the league secretariat could effectively supervise and conduct an interchange of police information concerning the illicit traffic, a function for which it is neither suited nor equipped and which it is not and cannot legally be authorized to perform.

As examples of inaccuracy in regard to the police side of the question, it may be pointed out that the book in listing governments definitely in a position to offer direct international police cooperation omits Canada and France, two of the most important and most active. Statements in the book in regard to specific cases of illicit traffic are mostly incorrect and misleading.

Inaccuracies in regard to existing administration include the statement that only three countries have abandoned the use of diacetylmorphine (heroin), whereas in July 1934, when the book was written, the use of this drug had already been abandoned or prohibited in nine countries.

The book discusses the two international boards that have executive and administrative functions under the drug treaties, the Supervisory Body and the Permanent Central Opium Board, but treats them as merely organs of the League of Nations. They are declared by the treaties that created them to be entirely independent of the league, and it is to this independence that they owe the cooperation of governments which has enabled them to function so effectively. Another inaccuracy is the statement that a representative of the United States participated in the selection of the first members of the Permanent Central Opium Board. It was not until five years later, when the independence of that body had been proved and well established, that the American government participated in the selection of its members.

On the basis of a total misconception of the nature and functions of the League Opium Advisory Committee, the work of that body is subjected to a most incomplete and unfair analysis. All its faults and errors—and they are not few—are emphasized, whereas its accomplishments are minimized or ignored.

Public Health Administration in the United States. By Willson G. Smittle, A.B., M.D., Dr.P.H., Professor of Public Health Administration, School of Public Health, Harvard University. Cloth. Price \$3.50. Pp. 458 with 23 illustrations. New York: Macmillan Company, 1935.

A clarification and summary of public health administrative practices in the United States has long been needed. Rosenau's *Preventive Medicine and Public Health* has been a scientific textbook in this field, as have the numerous contributions by Chapin, particularly *Sources and Modes of Infection*. The appraisal forms developed by the Committee on Administrative Practice of the American Public Health Association have given a skeletonized picture of what is being done, but it has remained for the author of this textbook to give a comprehensive summary of practices in official public health work and voluntary public health work and the relationship of these to the practicing physician. The book is comprehensive and complete and at the same time sufficiently concise so that its size is kept within reasonable bounds. The author has maintained a judicial attitude and has fairly set forth the advantages and disadvantages of various sorts of organization and different types of administrative practice. His proposed budgets are much more in line with reasonable possibilities in communities as they exist than those formerly proposed by Winslow. The author disclaims any pretension of presenting a philosophy of public health and yet he has done so in simply setting forth his opinions as to various practices. His chapter on the practicing physician and the public health department is particularly good. In this he takes the reasonable stand that the health officer has his duty to perform in protecting his community against disease and in the promotion of public health and that he ought to recognize that certain services are best performed by the practicing physician. On the other hand, he warns the physician that failure to accept his share of the responsibility or to meet opportunities in preventive medicine will place on the health officer the obligation to do what is necessary for the protection of the public health. He emphasizes over and over again that the relationship between health officer and practicing physician should be "one of mutual assistance and mutual advantage" and that "no health officer can carry on satisfactory work without the cooperation and whole hearted support of the organized medical profession of his community. No physician can practice

modern medicine in an effective way without the aid of a well organized, effective health department. The dependence of one on the other is mutual and success is contingent upon mutual understanding and confidence."

Silicosis and Tuberculosis. Observations on the Origin and Character of Silicotic Lesions as Shown in Cases Occurring on the Witwatersrand. By F. W. Simson, M.B., Ch.B., and A. Sutherland Strachan, M.A., B.Sc., M.D., Department of Pathology, The South African Institute for Medical Research, Johannesburg. Publications of the South African Institute for Medical Research No. XXXVI (Vol. VI). Paper. Pp. 367, 405 with 14 illustrations. Johannesburg: South African Institute for Medical Research, 1935.

During the years 1926 to 1933 inclusive, the lungs of 4,910 diseased South African miners and native laborers were examined by the authors. This number includes many persons who in life suffered from varying degrees of silicosis. The objective of the investigation was to develop evidence relative to a controversy, the points of issue of which are here taken from the authors' introduction.

"Can the nodular fibrosis which is recognized as the characteristic lesion in silicosis be produced as a simple response of the lung tissue to the presence of silicious dust?" or

"Is an element of tuberculosis always necessarily present in the original development of the lesions?"

The accumulated evidence is grouped into three sections, designated by the authors respectively as "The Histology of Silicotic Lesions from the Lungs of Diseased Gold Miners," "Results of Inoculation into Guinea-Pigs of Silicotic Lesions from the Lungs of Deceased Gold Miners," and "Preliminary Observations on the Mineral Residues Extracted from Silicotic Lungs." From their personal investigation and from their appraisal of pertinent literature, the authors accept an affirmative answer to the first question, namely, that silicosis may develop in the lung without the necessity of tuberculosis as contributory to the original development of the lesions. They do, however, recognize the high frequency of an infective factor and point out that with the naked eye it is possible to distinguish between "simple" and "infective" lesions. The authors submit that their accumulated evidence demonstrates

"That the retention in the lung of silicious dust is a necessary precursor to the development of silicosis, whether in its 'simple' or its 'infective' form, and that the amount of retained dust determines the degree of the silicotic process which follows."

"That, although some silicotic lesions are infective from the outset, in very many other lesions no evidence whatever of the influence of an infective factor is found, either at their origin or in their further progress. The latter lesions appear to be the outcome of a distinctive pathological reaction of the lung tissue to the presence of the retained silicious dust."

This publication reflects still further credit on the South African group of workers in dusty lung diseases. A carefully prepared brochure, presented with admirable restraint, it carries conviction that at least in the Witwatersrand district the pathology of silicosis is as described in this highly technical but no less engaging booklet.

Handbook of Physiology. By the late W. D. Halliburton, M.D., LL.D., F.R.C.P., and R. J. S. McDowall, M.B., D.Sc., F.R.C.P., Professor of Physiology, University of London, King's College. Thirty-fourth edition. Cloth. Price \$5.50. Pp. 871 with 386 illustrations. Philadelphia: P. Blakiston's Son & Co. Inc., 1935.

This volume is now in its thirty-fourth edition. The last edition was published in 1933. The present edition, like the others since 1928, is under the editorship of R. J. S. McDowall. The author points out that physiology has now developed such a tremendous fund of information that it is not possible for any medical student to acquire in the time at his disposal anything but a fraction of what is available. For this reason the present edition of Halliburton's book publishes in dark type numbers which the student ought to memorize as he goes along. Moreover, blank pages are provided at the end of the various chapters for the notes of the lectures given by individual instructors. The book has been kept quite up to date in all its editions and obviously needs no special recommendation. To the present edition the publisher adds an interesting historical note pointing out that the first edition of this book was developed by Kirkes in 1848, making a book of 705 pages with ninety-seven illustrations. The fourth edition (1860) carried the name of Mr

Savory, the sixth edition, that of Mr Baker Successive editions included the 1876 edition edited by Dr Klein, the tenth to the thirteenth (in 1892) edited by Mr Baker and Dr V D Harris, and then in 1896 came the selection of Professor Halliburton on the recommendation of Sir William Gowers Under Professor Halliburton the book passed through seventeen editions in twenty-nine years and sold a total of 116,000 copies

Consultations de cardiologie. Par Georges Marchal médecin de l'Hôpital Tenon Préface du Docteur Ch Laubry médecin de l'Hôpital Broussais Paper Price 25 francs Pp 227, with 13 illustrations Paris Masson & Cie 1935

This presents thirty case histories with the symptoms, physical observations, laboratory examination and the treatment given under the care of the author There are two interesting cases in the series not commonly encountered, a syphilitic pulmonary arteritis, or Ayerza's disease, with excellent roentgenographic studies, and another of cardiac failure as a result of filariasis There are a number of points of diagnosis and results of treatment that do not conform to American views The author discusses a case of rheumatic pancarditis described as cured by treatment with sodium salicylates administered orally and intravenously Another case of syphilitic myocarditis with congestive heart failure is described which, according to our standards, would be classified as hypertensive vascular disease with systemic syphilis The book is of interest only from the standpoint of the citation of thirty rather interesting case histories and presents a fair concept of the present French view of the various types of heart disease.

The Doctor and the Public A Study of the Sociology Economics Ethics and Philosophy of Medicine Based on Medical History By James Peter Warbasse M.D Cloth Price \$5 Pp 572 with 19 illustrations New York Paul B Hoeber Inc. 1935

After a surgical practice of a quarter of a century, Dr Warbasse is devoting himself to the economic aspects of medical work. He expresses his point of view by saying that the solution of the medical problem is to be found in expanding the functions of the medical profession and in increasing the employment of physicians Dr Warbasse seems inclined to favor voluntary socialization of medicine without political control—a handsome ideal but certainly, in the present state of our civilization, only an ideal In this volume he traces the history of health protection from the earliest times giving special attention to the development of medicine among the Greeks and among the civilized countries of the middle ages More than two thirds of his volume is thus devoted to a brief history of the development of scientific and preventive medicine. With chapter 8 he begins a discussion of medical education of the public, quoting largely from the reports of the Committee on the Costs of Medical Care In chapter 10 he turns his attention to his main thesis Here he outlines the organization of various forms of group practice in the United States, pointing out that some form of socialization of medicine is coming and urging the development of a system under which doctors would be on salaries and employed by groups of patients under contractual relationships

Living Along with Heart Disease By Louis Lerin M.D Cardiologist to the St Francis Hospital and New Jersey State Prison Hospital Trenton N J With a foreword by Thomas M McMillan M.D Associate Professor of Cardiology Graduate School of Medicine University of Pennsylvania Cloth Price \$1.50 Pp 126 New York Macmillan Company 1935

The purpose of the author 'is to present to the reader a simplified explanation of the various aspects of heart disease, with the ultimate hope of instilling sane optimism in the patient's philosophy of heart disorders' Medical books for the layman are difficult to write especially if they are intended for the reader who is also a sufferer from the diseases described. This small book, however, will probably do no harm to the cardiac patient who reads it and may interpret heart disease helpfully to certain patients The discussion includes chapters on the fear of heart disease, the types 'leaky' hearts myocarditis hypertension, heart pain, treatment, questions and answers, the philosophy of heart disease, and the physician It is a good summary of heart disease in general and will give the layman a sound point of view on the whole subject Unfortunately, heart disease is not a single entity and it would appear some-

what difficult for the practicing physician to decide for whom to prescribe this book The handling of patients in practice is so individual a matter that the amount and type of explanation of their disease which seems justified must be varied to suit each case Does it profit the patient with angina pectoris to read about subacute bacterial endocarditis or cardiac arrhythmia, or to know the procedures used in the treatment of congestive failure which he may sometime experience after a coronary thrombosis? The style of the book is breezy and at times dramatic, but it suffers from an attempt at popular appeal through the use of slang and literary gymnastics and contains a few errors of fact However, these are of minor importance and are outweighed by the amount of helpful advice that is given

Experimental and Clinical Researches on Angina Pectoris and Its Surgical Treatment. By Rene Leriche FRCS F.A.S.A. Professor of Clinical Surgery Strasbourg Macewen Memorial Lecture 1934 Paper Price 1/6 Pp 24 with 7 illustrations Glasgow Jackson Wylie & Co 1935

In this lecture Leriche presents a summary of his views concerning angina pectoris and its surgical treatment based on experimental and clinical studies, which, with Fontaine, he has carried on for some ten years For the details of these studies as well as for a comprehensive view of the whole subject of the surgical treatment of angina the reader must look elsewhere, for the author confines himself strictly to the topic, viz, his own conclusions based on his own work Leriche accepts the coronary origin of angina yet considers spasm a prominent feature in some cases Pain, he says is a symptom and not the real disease He discusses the physiology of the nervous mechanism involved in pain, also the importance of anastomosis as a compensatory factor There are still many questions to be solved, such as the cause of thrombosis, which is the "greatest unknown factor in arteritis" The indications for operation are considered The operation of choice is the removal of the stellate ganglion His conservatism is shown by the fact that in nine years he has performed but eighteen operations The results he regards as encouraging The article is a model of clear, terse writing and will be consulted by all who are trying to familiarize themselves with this important subject.

Fifty Years a Surgeon By Robert Tuttle Morris Cloth Price \$3.50 Pp 347 New York E P Dutton & Co Inc, 1935

The name of Robert T Morris is familiar to most American medical readers Through our generation he has contributed largely to the literature of medicine and to its letters His career began just before the coming of the age of asepsis, so that he is able to tell us in his excellent style what surgery was like in that early period. He begins his book in his early days, which depict his interest in the woods and in nature, an interest which has no doubt made happy his declining years Then comes the story of his medical education and his early years at Bellevue Hospital The concluding chapters in his book concern such interesting topics as osteopathy, fads and cures, psychoanalysis sex and birth control professional jealousies and fee splitting On each of these subjects he ventures his personal opinion and casts the light of his experience It should of course, be recognized that these chapters do not aim to be authoritative or necessarily comprehensive. The book is personal in every sense of the word and, as such, one of the most interesting autobiographic documents that has been recently available

Modern Criminal Investigation By Harry Söderman D.Sc Head of the Institute of Police Science School of Law, University of Stockholm Sweden and John J O Connell Deputy Chief Inspector New York City Police Department Cloth Price \$3 Pp 481 with 110 illustrations New York & London Funk & Wagnalls Company 1935

The biologic laboratory comes more and more into the investigation of the methods of crime Microscopic studies of hair, finger prints, precipitin and agglutinin studies of the blood, anthropologic measurements, are all within the range of biologic study In this volume the author considers all these methods as well as many others and relates a considerable number of interesting medicolegal cases in which their application was of significance. The book is up to date and certainly should be in the hands of every judge, lawyer and physician who is interested in medicolegal work.

Medicolegal

Pneumoconiosis Following Inhalation of Limestone Dust, Employer Not Liable—Christopher had been an employee of the defendant company, which operated a rock quarry and stone crusher. After he had been so employed for a year, ill health compelled him to quit work. Two months later he died. The plaintiff, administrator of Christopher's estate, sued the defendant company, alleging that death was caused by the inhalation of limestone dust. From a judgment dismissing the petition, the plaintiff appealed to the Court of Appeals of Kentucky. The plaintiff alleged that the harmful and deadly effect of the inhalation of limestone dust and small particles of limestone rock was unknown to his intestate, Christopher, but was known to the defendant, Christopher's employer, or that the defendant could have known of it by the exercise of ordinary care, and that the defendant negligently compelled Christopher to work in the dust and small particles of limestone rock and did not furnish him with a mask to go over his mouth and nose to prevent the inhalation of such dust and particles. The Court of Appeals, however, was unable to find any statute requiring the defendant to provide Christopher with such a mask and could find in the record no allegation that masks had been tried and found capable of advantageous use, or of any use, in work of the character of that in which Christopher was engaged, or that any men anywhere had ever used masks in that sort of work. The needs of society, said the court, may be such that very dangerous work must be undertaken to supply those needs. Men have the right to employ other men to do such work, and if in the doing of it the servant is injured, the liability of the master, if any, must be found not in the inherent hazards of the work but in some negligence of the master in the way that he has the work done. An employer is not required to adopt a particular method because it affords greater safety for the employee, but he is required to adopt the usual and customary method employed by ordinarily prudent men in like work under similar circumstances. The judgment in favor of the defendant stone company was affirmed.—*Christopher's Adm'r v Blanton Stone Co., Inc* (Ky) 80 S W (2d) 590

Hospitals Liability for Self-Inflicted Injury of Mentally Disordered Patient—The defendant hospital association maintained a general hospital for medical, surgical, obstetric and pediatric cases. On February 15 the plaintiff was brought to the hospital by his brother and was admitted as a patient. The brother seems to have named Dr. Richard Johnson as the patient's attending physician, and Dr. Johnson, on being notified of the plaintiff's admission to the hospital, prescribed a sedative, strict rest in bed, no visitors, and other measures appropriate for a mentally distressed patient. No history of the case was taken by any one on behalf of the hospital. The patient was cared for in a ward room on the second floor until February 18, because no single room was available. On that day, when a single room on the third floor became available bars were placed on the outside of the lower half of the window in such a way as to prevent the lowering of the upper sash more than a few inches, and the patient was removed to it. The placing of the bars at the window, it was explained, was an action taken in all cases of nervous patients. On the floor where the patient was, there were then a supervisor, a graduate nurse and four student nurses. According to the record, they called at the patient's room frequently. He had been last visited by one of them some time after 4 o'clock in the afternoon, when shortly thereafter and about three hours after his transfer to the safeguarded room, he broke the glass in the upper sash of the window and jumped out. The patient had manifested evidences of agitation but apparently no discoverable evidences of a suicidal tendency. No physical restraints were applied. No nurse was in constant attendance. The patient was severely injured by his fall, and by his guardian he sued the defendant hospital association. The jury returned a verdict in his favor and the hospital association appealed to the Supreme Court of Minnesota.

If the actions of a patient, said the Supreme Court are such that a reasonably prudent person should anticipate an

inclination on his part to attempt to escape or to commit suicide, reasonable care should be exercised to prevent such an act. In the opinion of the court, however, the known facts in this case were not such as to charge the hospital association with negligence in not recognizing that the patient contemplated escape or suicide. A reasonably prudent nurse or intern in a general hospital could not have anticipated that the patient, under the circumstances, would suddenly jump out of bed, step up on the window sill, climb over the large lower half of the glass, break the pane in the upper half, and throw himself out of the window. The plaintiff's own attending physician knew as much as the hospital authorities did, or more, concerning the plaintiff's condition, and yet he gave no instructions to apply restraints nor did he direct that the bars should be put on the windows.

The nurses and interns at a general hospital, said the Supreme Court, are charged with the duty of carrying out the instructions of the attending physician, except in cases of emergency. When a patient enters a hospital on the advice of his physician, he has the right to expect that the instructions of his physician will be complied with. He relies on the skill of his own physician, but he knows nothing of the ability of the interns and nurses. When an emergency arises it is, of course, incumbent on the nurses or interns to exercise their own judgment until report can be made to and instructions received from the attending physician. Such, the evidence shows, was the practice at the defendant hospital. The rule has been laid down in *Byrd v Marion General Hospital*, 202 N C 337, 162 S E 738, as follows:

The great weight of authority however establishes the principle that nurses in the discharge of their duties must obey and diligently execute the orders of the physician or surgeon in charge of the patient unless of course such order was so obviously negligent as to lead any reasonable person to anticipate that substantial injury would result to the patient from the execution of such order or performance of such direction. Certainly if a physician or surgeon should order a nurse to stick fire to a patient no nurse would be protected from liability for damages for undertaking to carry out the orders of the physician. The law contemplates that the physician is solely responsible for the diagnosis and treatment of his patient. Nurses are not supposed to be experts in the technique of diagnosis or the mechanics of treatment.

The court was unable to agree with the plaintiff that the defendant hospital association, through its employees, should have ascertained the plaintiff's condition before admitting him to the hospital. The plaintiff was left at the hospital by his brother, who gave no information concerning his ailment. The instructions received from the plaintiff's physician, who presumably was aware of his patient's condition, indicated nothing more than that the patient was in need of rest. So far as the record shows, the patient's physician was not an employee of the defendant hospital association and his negligence therefore, if there was any, cannot be imputed to the association. If the defendant association had maintained and operated a hospital for the purpose of treating and curing diseases, physical and mental, and had its own staff of physicians and specialists for that purpose, probably it would have been its duty to ascertain all it could concerning an entering patient's previous history, a rule especially apt with respect to hospitals specializing in the cure of mental disorders. The hospital maintained by the defendant association, however, was merely a place to which physicians sent patients under their own care. The hospital association did not take on itself the curing of any disease, either by medical treatment or by surgical operation. The hospital attendants performed routine services and carried out the instructions of the attending physician. Patients were not furnished with a nurse in constant attendance, unless requested. Relatives of the patient must be charged with a knowledge of these facts. It would be a harsh rule indeed, said the Supreme Court, that would charge the authorities of a general hospital to go in search of the relatives of every patient entering it under the care of a physician of his own or a relative's selection, and ascertain, independently of the attending physician, the nature of the patient's ailment and then to exercise their own judgment as to treatment required.

The Supreme Court reversed the judgment of the trial court in favor of the plaintiffs and ordered that, notwithstanding the verdict, judgment be entered for the defendant.—*Mesdahl v St. Luke's Hospital Ass'n of Duluth (Minn.)*, 259 N W 819

Workmen's Compensation Acts Ophthalmia Due to Exposure a Compensable Injury—The plaintiff was employed by the defendant to operate a machine removing snow from the highway. His work required him to keep his eyes constantly on the snow. On March 23 he worked at his task for twelve hours, the day being "quite warm for that time of year" and the sun shining brightly. At the end of the day he was burned about the face, as if sunburned, and his eyes were inflamed. The skin of his face desquamated. His eyes grew worse, and during the week an ulcer developed in the right eye and on or about May 18 another developed in the left eye. There was a severe infection and ulceration on the conjunctivae and the corneas of both eyes, with the appearance of pus. The plaintiff instituted proceedings against his employer, under the Nebraska workmen's compensation act. An award in his favor by the compensation commissioner was sustained by the district court, and the employer appealed to the Supreme Court of Nebraska.

The condition of the plaintiff, said the Supreme Court, was produced by "snow blindness" or "snow ophthalmia." The condition is rare in the climate in which the plaintiff was working and therefore the court concluded that it was unexpected and unforeseen. There was no dispute as to the existence of "a burning" in snow blindness, and the injury to the eyes of the plaintiff was therefore violence to the physical structures of the body. The injury said the Supreme Court, was due to the reflection of ultraviolet rays of sunlight from the bright snow which had to continue for several hours before it manifested itself or became known to the person exposed. In this instance, the condition manifested itself on the day of exposure and therefore may be said to have occurred suddenly. In the light of these facts, the judgment of the court below sustaining the award of the compensation commissioner was affirmed.—*Hayes v McMullen (Neb)*, 259 N W 165.

Malpractice Degree of Care and Skill Required, Qualifications of Expert Witness—The physician-defendant treated oblique fractures of both bones of a patient's leg. Three weeks after reducing the fractures he massaged and manipulated the foot and ankle. Immediately thereafter his patient complained of a severe tearing sensation in the leg. After her complaint no roentgenogram was made until after six weeks. A roentgenogram then showed the fragments to be out of place and not united. After an operation which included bone grafting, union was effected and the wound healed. The record shows that the patient subsequently died, but the time and cause of death is not stated and there is nothing to indicate that it was connected with the injury described. The plaintiff individually and as administratrix of the estate of the deceased patient, sued the defendant-physician. From a judgment holding that no cause had been established the plaintiff appealed to the district court of appeal, second district division 2, California.

The plaintiff based her suit on the claim that the physician-defendant caused the fragments of the broken bones to slip from their places when he massaged and manipulated the foot and ankle, and that he failed to have roentgenograms taken and in other respects to use ordinary care and skill in determining whether the fragments were or were not in proper position. The court of appeal drew a distinction between proper treatment and the care and skill required by law. "Proper treatment," said the court, implies that no error shall be committed thereby that an approximate perfect result will be produced, that such result is guaranteed whereas the law demands only that the physician use reasonable care to attain such approximate perfection. In the absence of evidence to the contrary the law will presume the exercise of a reasonable degree of care and skill. The absence of skill is not presumed from the mere failure of treatment to produce a cure. If a physician possesses a reasonable degree of learning and skill and in the treatment of the patient's injury, exercises ordinary care and skill, measured by the standards of his profession in the same locality he is not liable for the results that follow. It is a rule, said the court, that proof of negligence or lack of care or skill on the part of a physician in

a malpractice case consists only in the opinion of experts. To qualify as an expert in a malpractice case, the witness must show not only that he possesses learning and knowledge on the subject of inquiry, sufficient to qualify him to speak with authority on the subject, but also a familiarity with the treatment and degree of care and skill of other practitioners in the locality in question sufficient to qualify him to say whether or not the defendant's treatment was consistent with what other physicians in the exercise of reasonable care might do under similar circumstances. As the expert called as a witness by the plaintiff failed to show that he possessed sufficient familiarity with practice in the locality with respect to treatment of oblique fractures of the leg bones, the trial court properly sustained an objection to his competence.

Viewed in the light most favorable to the plaintiff, the evidence wholly failed to establish a case of malpractice. The motion of the defendant to dismiss the case for lack of evidence was properly granted.—*Rasmussen v Shuckle (Calif)*, 41 P (2d) 184.

Narcotics Possession Unlawful Although Obtained on Physician's Prescription—The defendant, according to the record, applied to a physician for a remedy for arthritis. The physician testified that the defendant had contracted a cold, had a high fever and was suffering considerable pain, and that because of the defendant's ailments he prescribed one-half grain tablets of morphine sulfate and five grain tablets of sodium salicylate. The defendant was thereby enabled to obtain twenty tablets of morphine sulfate containing one-half grain each. He was later arrested and it was found that he had consumed or otherwise disposed of, within eight hours, twelve such tablets. Eight tablets were found in his possession and he was charged with unlawful possession under the Kansas law. Two physicians who examined him after his arrest testified that there was no visible sign of arthritis and that his actions while in custody presented the picture of a drug addict. The analyst of the state food laboratory testified that it would be impossible for a normal person, one not addicted to the use of narcotic drugs, to consume twelve one-half grain tablets of morphine sulfate within eight hours. The defendant was convicted and appealed to the Supreme Court of Kansas.

The fact that the defendant procured the narcotics found in his possession on the basis of a prescription issued to him by a physician, said the Supreme Court, does not exempt him from the operation of the statute making the possession of narcotic drugs unlawful if he misrepresented his condition to the prescribing physician. The quantity of narcotic drugs procured and the use of them by the defendant tended to show an unlawful use whether the defendant used them himself or sold some of them to others. The court, being convinced that the defendant had obtained by subterfuge the narcotic drugs in his possession, affirmed the judgment of conviction.—*State v Strode (Kan)* 42 P (2d) 603.

Privileged Communications Testimony of Examining Physician Inadmissible, Presence of Third Person as a Waiver—The plaintiff, as beneficiary, sued the Policy Holders Life Insurance Association for the benefits promised in a policy of insurance issued to his wife. To prove that the insured wife, in her application for the policy, made misrepresentations concerning her previous health, the insurer sought to introduce the testimony of a physician who examined her some time after the policy had been issued. The trial court excluded his testimony on the ground that it was privileged and therefore inadmissible under the California statute of privileged communications. Judgment was rendered for the plaintiff, and the insurer appealed to the California district court of appeal, second district, division 1.

According to the testimony, the insured, some time after her insurance policy had been issued, applied to the Coffey-Humber Clinic for treatment. There she was examined by the physician whose testimony was excluded by the trial court. The clinic is maintained by the W. K. Kellogg Foundation, but this physician was not employed by the clinic or by the foundation but by W. K. Kellogg personally. His sole duty was to examine prospective patients and at a subsequent time to reexamine such as were accepted, but only for the purpose of determining

the efficacy of the treatment given by the clinic. He had nothing whatever to do with directing or administering treatment. The physician whose testimony was excluded made a physical examination of the insured in the presence of the physician's stenographer, took her history and reported it to the Kellogg Foundation and to the clinic. It is fair to assume, said the district court of appeal, that a patient applying to the Coffey-Humber Clinic for treatment was not treated solely on the patient's statement that he or she had cancer. The physician whose testimony was excluded had regular hours at the clinic and made appointments with patients. No patient could receive treatment unless examined by him or some other physician who performed similar duties. That examination, the court of appeal was convinced, was an indispensable part of the treatment given. The California statute of privileged communications provides, among other things, that—

A licensed physician or surgeon cannot, without the consent of his patient be examined in a civil action as to any information acquired in attending the patient, which was necessary to enable him to prescribe or act for the patient.

The proffered testimony of the examining physician was within the scope of the statute and was properly excluded.

The insurer contended that the insured, by permitting the presence of the stenographer during the examination, waived her privilege. The mere presence of a third person, the court of appeal said, does not mean that the privilege has been waived as to the physician. The capacity in which the third person is present controls. The court of appeal held that where a third person is present as an agent of the attending physician, the privilege is not waived so far as relates to the attending physician. Because the stenographer was not offered as a witness, the court did not determine whether she could or could not have been required to testify. The judgment of the trial court against the insurer was affirmed—*Kramer v Policy Holders Life Ins Ass'n (Calif)*, 42 P (2d) 665.

Dental Practice Acts Revocation of License for Default in Annual Registration, Injunction to Prevent Unlawful Practice—A law requiring a dentist to register annually, paying a fee for doing so, and authorizing the irrevocable cancellation of his license if he fails, is valid, according to the Court of Appeals of Kentucky, even though the defaulting dentist was licensed when annual registration was not required, was absent from the state when the annual registration law was passed, had been continuously absent ever since and was given no notice of the prospective cancellation of his license. Equity will enjoin such an unlicensed dentist from practicing, even after the grand jury has failed to indict him for the unlawful practice of dentistry—*Commonwealth ex rel Attorney General v Pollitt (Ky)*, 80 S W (2d) 543.

Malpractice Cerebral Hemorrhage Attributed to Chiropractic Adjustment—This is the third opinion rendered by the Supreme Court of Florida in this case, and the case is as yet unsettled. Briefly, the plaintiff's wife died from a cerebral hemorrhage following chiropractic adjustments of her spine by the defendant-chiropractor. The plaintiff charged that the defendant negligently used so much force and violence in attempting to adjust the vertebrae that he ruptured a vessel at or near the base of his patient's brain and thereby caused a hemorrhage into and around her brain and spinal cord, from which his patient died. The plaintiff obtained a judgment in the trial court, but on appeal the Supreme Court of Florida held that although the evidence was sufficient to warrant a finding that death resulted from the chiropractic adjustments, it was insufficient to prove that those adjustments were done in an unskilful or negligent manner. The Supreme Court was induced, however, to give a rehearing, and on that rehearing it held that the testimony of physicians that the rupture of the blood vessel in the brain was caused by violence, together with the defendant-chiropractor's own testimony that a properly made adjustment could not have caused such a rupture, was legally sufficient to sustain a verdict against the chiropractor. The court on this occasion affirmed the judgment of the trial court in favor of the plaintiff. *Foster v Thornton* 152 So 667, abstr THE JOURNAL, Oct 20, 1934 p 1260. Again the Supreme

Court granted a rehearing and reviewed the evidence for a third time. This time the court was unable to reach a conclusion, three justices being in favor of affirmance of the trial court's decision and three for reversal. Ordinarily, in such a situation, the judgment of the lower court would be affirmed, but in this case the Supreme Court thought that the ends of justice would be better served by remanding the case for a new trial, and it was so ordered—*Foster v Thornton (Fla)*, 160 So 490.

Hospitals Abscesses Following Hypodermic Injections by Nurse—The plaintiff entered the defendant hospital as a paying patient, under the care of her own physician, for care during childbirth. Her physician, she alleged, instructed a nurse employed by the hospital to administer a hypodermic injection of magnesium sulfate in the fleshy part of each arm, whereas the nurse administered those injections in the large muscles of the hips or thighs. Abscesses developed at the sites of the injections. The patient sued the hospital, contending that it failed to provide her with a competent trained nurse. The trial court gave judgment for the patient, and the hospital appealed to the Supreme Court of Oklahoma.

There was no substantial dispute except as to whether the nurse was instructed by the attending physician concerning the site of the hypodermic injections. All medical witnesses testified that the usual site of injection was the large muscle of the hip or thigh, but the patient's attending physician testified that he preferred to give such injections in the arms. There was no evidence of error in the nurse's technique of administration. Neither was there any evidence to show that similar abscesses would not have followed injections into the arms. Nothing in the evidence indicated that the site of injection had anything to do with the abscesses, except as it determined their location. In the opinion of the Supreme Court, the evidence indicated only that, except for the nurse's negligent act, the abscesses would have occurred in some part of the body other than the places at which they did occur. There was no evidence to show that the injury would have been less likely to occur or be less severe if injections had been made in the arms. The evidence did not show that the nurse's negligence was the proximate cause of the injury.

The judgment of the trial court was reversed, with directions to enter judgment for the defendant hospital—*Masonic Hospital Association of Payne County v Taggart (Okla)*, 43 P (2d) 142.

Current Medical Literature

AMERICAN

The Association library lends periodicals to Fellows of the Association and to individual subscribers to *THE JOURNAL* in continental United States and Canada for a period of three days. Periodicals are available from 1925 to date. Requests for issues of earlier date cannot be filled. Requests should be accompanied by stamps to cover postage (6 cents if one and 12 cents if two periodicals are requested). Periodicals published by the American Medical Association are not available for lending but may be supplied on purchase order. Reprints as a rule are the property of authors and can be obtained for permanent possession only from them.

Titles marked with an asterisk (*) are abstracted below.

Prophylactic Use of Whole Blood in Anterior Poliomyelitis—Stokes and his associates discuss and tabulate the results of prophylactic injection of parents' blood, pooled convalescent serum and pooled adult serum in 2,179 children in Philadelphia. An attempt to analyze statistically the incidence of poliomyelitis in a group of 620 children who received injections in a certain census tract area of Philadelphia, and its relation to the group who did not receive injections in the same area, is described. A small group of eleven children who contracted poliomyelitis from five to eighteen days following the injection of whole blood or serum is described. The mild nature of the attack is emphasized as apparently favoring such prophylaxis, since residual paralysis developed in only one child. The authors state that, if one assumes that parents' whole blood usually contains as large amounts of immune bodies against poliomyelitis as does pooled adult serum, the advantage of a readily available supply for immediate use probably will determine its choice. This procedure is particularly applicable in the presence of a widespread epidemic without adequate preparation for it. If in the future passive immunization with serum or whole blood proves to be effectual, it is possible that the availability of lymphic serums may rectify such lack of preparation. They believe that, in view of the experiences in Philadelphia and in Bradford and the favorable clinical impressions derived from them, parents' whole blood should be used as a prophylactic measure whenever possible in large epidemics of poliomyelitis, both for the sake of the children and for the purpose of accumulating further statistics regarding its value. Over the period of an epidemic more than a single injection would seem advisable since passive immunization probably does

not persist for more than from four to six weeks. Lymphic human serums of high neutralizing value against the virus of poliomyelitis which apparently retain their antibody titer, should be made available wherever epidemics arise.

Tubercle Bacilli in Infants of Tuberculous Mothers—

Siegel and Singer studied fifteen new-born infants of tuberculous mothers for evidence of the transmission of tubercle bacilli by way of the umbilical vein. Cultures of umbilical blood by the Loewenstein method were negative for tubercle bacilli in fourteen infants. In the one in which the culture of umbilical blood was positive, the placenta had a large tuberculous area. The child was born prematurely at seven months and died three hours after birth with no demonstrable lesions on postmortem examination. A culture of the heart blood was strongly positive for tubercle bacilli. The mother died of tuberculosis eighteen hours after delivery. In the fourteen cases in which cultures of umbilical blood gave negative results, the placentas were normal on routine macroscopic examination and on microscopic study of several sections. The new-born infants in this group showed no evidence of tuberculosis. Four died within one month and cultures of the heart blood and of specimens from the liver, spleen and lungs were negative for tubercle bacilli. Ten are normal, as shown by repeated roentgenograms of the chest and results of intracutaneous tests with 10 mg of tuberculin. Of the fourteen mothers in this group, nine had advanced pulmonary tuberculosis and five had minimal, nondestructive lesions. The tuberculous process in those mothers with advanced phthisis progressed during the postpartum period and caused death in five instances. Those with minimal lesions showed no progression after labor. Cultures of blood taken before and after labor from five mothers with advanced pulmonary tuberculosis were negative for tubercle bacilli by the Loewenstein method.

Maldevelopment and Malescent of Testes—Dorff gives the results in fourteen boys having hypoplastic genitals who were treated with the anterior pituitary-like gonadotropic principle from the urine of pregnant women (and with the anterior pituitary growth hormone). In seven of eight patients with undescended testes there was some increase in size and descent, while in the other patients with hypoplastic testes there was a double or triple increase in size. The first apparent sign of the effectiveness of the therapy was usually a blushing or pinkish coloration of the scrotum and often of the penis. With the enlargement of the scrotum, an increase in the size of the testes was observed and, later, of the penis. There appeared blond, fuzzy pubic hairs, which later became pigmented, more numerous and longer. This progression of development was noticed even in the younger children. It was necessary to administer a large quantity of extract before beneficial effects were evident and a larger number of total rat units before effectual results were obtained. The response was slow, and very little change could be observed during the first few months of therapy. The most efficacious dosage was found to be a large dose of anterior pituitary-like gonadotropic principle from the urine of pregnant women (250 rat units) given from three to five times a week until there was a genital response, and then the same amount given three times a week. There were two predominant types of persons in the author's series: those with adiposogenital dystrophy and those with mild or masked hypothyroidism. A lowered basal metabolic rate, evident in patients with primary hypogonadism and in those with hypothyroidism, will remain low, even after the administration of the anterior pituitary-like gonadotropic principle, although there may be a slight increase. The basal metabolic rate at the onset of treatment was on the minus side, and the author feels that under true basal conditions and on several repetitions of this test there would be still lower minus rates. If there are no mechanical factors to obstruct descent, good results can be anticipated and obtained in patients with maldeveloped or maldescended testes. Also, there is the possibility of developing an apparently absent testis, and therefore treatment should be given. Treatment may be started at any time before puberty. However, patients closer to puberty show a more rapid response. Although the author discontinued thyroid therapy during his study, he thinks that it should be given along with the anterior pituitary-like gonadotropic principle in order to obtain the best

results in the patients with mild or masked hypothyroidism. Patients with hypoplastic and undescended testes should not be submitted to surgical procedures until a course of intensive treatment with the anterior pituitary-like gonadotropic principle has been instituted for one year without success.

Effect of Artificial Fever on Pulse-Volume Changes of Finger—Johnson and his associates observed an increased pulse-volume change with all types of artificial fever except foreign protein, which gave a primary decrease of the pulse-volume change associated with the chill. They interpret the increased pulse-volume change as increased circulation, a result of the vasodilatation and probably increased cardiac output. The effect of artificial fever on peripheral circulation, when induced by general heat with prevention of heat loss, was about the same with all the methods used. The finger volume change increased from about 0.01 cc. control to from 0.06 to 0.08 cc. The maximal circulatory response occurred at a temperature considerably lower than the maximum used. The amplitude of the excursions measuring the circulatory response showed marked variations as the temperature was maintained, which they interpreted as due to instability of the vasomotor system and instability of the heat regulating mechanism which is intimately associated with the vasomotor system. This indicates that there may be an optimal temperature at which a maximal circulatory response occurs. This suggests that high therapeutic fevers up to 106 F as often used are too high unless factors other than circulation play a part and are brought out only by fevers above the optimum. The circulatory response to artificial fever induced with foreign protein differed from that obtained with artificial fever induced by external heat. Foreign protein uniformly in five patients gave a primary vasoconstriction associated with the chill and followed by a vasodilatation. The vasodilatation was never as great as that produced by the other methods unless heat loss was prevented by insulating the body and the fever maintained. Clinically good results are obtained with foreign protein therapy in spite of the fact that the peripheral circulatory response is not as great with fever induced by other methods. The fundamental difference in the results of foreign protein fever and that produced by external heat is that the vasoconstriction and vasodilatation of foreign protein fever is probably of central origin, while the vasodilatation with fevers produced by other means is chiefly of peripheral origin. Artificial fever induced by external heat is dangerous unless proper precautions are taken, and even then some patients do not tolerate fever well, particularly those with impairment of the cardiovascular system. Proper equipment is paramount. A recording thermometer should be used so that an accurate observation of the temperature can be had at all times. A physician should be present at all times, and means for emergency treat-

ment of heat exhaustion should be available. The ability to tolerate this type of artificial fever seems to be related to the cardiovascular reserve. The question of how long the fever should be maintained is debatable. The authors feel that it should not be run to the point of exhaustion. Regarding the best method of inducing artificial fever from external heat, they believe that the ordinary electric light cabinet is probably the best. The most dangerous method is probably the hot water bath.

Metabolic Rates in Therapeutic Fever—Kopp determined the metabolic rates of seven patients having neurosyphilis in whom fever was induced by artificial means. In six patients, in whom fever was induced by the combined method of diathermy current, electric cabinet and hot moist air, determinations were started about two and one-half hours after a light breakfast. In the seventh patient, in whom fever was induced by diathermy current, electric cabinet and hot moist air, a method combining the diathermy current, the electric blanket and hot moist air, electric blanket and mixed typhoid vaccine, all determinations were made under basal conditions. An increase in the metabolic rate occurred when fever was induced by the combined method of diathermy current, electric light cabinet and hot moist air. Though a rather suggestive linear relationship was present, fluctuations of a fairly marked degree occurred at different temperature levels when the group is taken as a whole. This may be due to individual variations in the degree of discomfort manifesting itself especially by hyperpnea, the metabolic rates at higher levels paralleling, as a rule, the amount of hyperpnea present. Repeated metabolic rates obtained on one patient under basal conditions in a series of experiments during which body temperature was raised by similar methods and maintained at different levels from one to three hours revealed a fairly uniform increase in body metabolism for each degree of temperature rise. The removal of the insulating hot, moist air blanket when the body temperature had reached its desired height was followed in nearly all cases by a rather steep fall in metabolic rate whether body temperature remained at the same level, fell or even rose. Metabolic rates for similar temperature levels were higher when the temperature was rising than when falling. The diathermy current alone over short intervals had no specific effect on the basal metabolic rate, provided no rise in body temperature occurred. Alteration of the frequency of the diathermy current at increased temperature levels also caused no appreciable change in the metabolic rate. The increases in metabolic rate obtained on the one patient, in whom a rise of temperature was induced by the five different methods, showed a rather striking parallelism and did not differ much from the accepted rise of 7.2 per cent for each degree Fahrenheit, except in fever induced by diathermy current alone. In the latter the average rise in metabolic rate was 2.4 per cent and 3.9 per cent for each degree of fever. The rapidity of the rise in body temperature played no part in the results obtained. Repeated fever treatment of one patient over a period of seven months had no residual effect on the basal metabolic rate.

Bone Changes in Sickle Cell and Erythroblastic Anemia—Grinnan observed four cases of sickle cell and five of erythroblastic anemia, all of which showed roentgenologic bone changes. The four cases of sickle cell anemia showed thickening of the frontal parietal, occipital and temporal bones, with thinning of the inner tables and very thin or absent outer tables. The skull changes found in sickle cell anemia and erythroblastic anemia are so similar that they cannot be differentiated by roentgen examination alone. Changes of the long bones were found in only one case of sickle cell anemia. They consisted of cortical thinning, expansion of the shafts and medullary trabeculations. Striations were also present in the pelvis and scapulas. The bone changes seen are not typical of sickle cell anemia alone but also resemble those of erythroblastic anemia. The five cases of erythroblastic anemia showed bone changes in varying degrees depending on the age of the patient and the duration and severity of the disease. Three of the erythroblastic cases showed thickening of the skull and extensive changes in the long bones and other bones of the skeleton. The earliest definite bone changes found in erythroblastic anemia occurred in the metacarpals and skull. Four of the cases of erythro-

blastic anemia occurred among children of Italian parentage. All four cases of sickle cell anemia occurred in Negro children. One case has been presented because it shows that the presence of erythroblasts, even for a relatively short time, produces medullary thickening of the skull. This condition occurred in a child of English-Irish parentage, while it is generally accepted that this occurs only in the Mediterranean races. The bone changes found on roentgen examination in sickle cell anemia and erythroblastic anemia are very similar and are not alone diagnostic of either condition.

Bone Changes of Leukemia in Children—Baty and Vogt made roentgenograms of part or all the skeleton in forty-three cases of leukemia. The most frequent change was a narrow, transverse zone of diminished density just proximal to the metaphysis of the long bones. This zone or line varied from 2 to 5 mm. in width and was most marked in bones in which growth is rapid, as in the lower ends of the femurs and tibiae. It seemed relatively more prominent as the disease progressed. The line was present in the bones of 70 per cent of the forty-three cases. It was present in the bones of sixteen patients less than 3 years of age and in twenty-nine less than 6 years of age. In attempting to analyze the occurrence in the different types of leukemia, it was found that the zone was present in 80 per cent of the cases of myeloid leukemia and in 65 per cent of the cases of lymphoid leukemia. This zone of diminished density is not peculiar to leukemia and its production is not entirely clear. Infiltration and erosion of bone by masses of leukemic cells probably plays some part, particularly in instances in which it is most marked. Microscopic sections of some of these bones showed leukemic infiltration in the region bordering the metaphysis, but the masses of infiltrating cells were not definitely greater than in other regions. The line of rarefaction is very similar in location and in appearance in the Trümmerfeld zone, which is demonstrable in roentgenograms of the bones in scurvy. Neuroblastoma with generalized miliary metastases may simulate rather closely the more advanced changes of leukemia. In both diseases the roentgenograms of the skull may show a diffuse granular mottling and the cranial sutures may be separated as the result of increased intracranial pressure. The pelvis and spine may also give much the same roentgen picture in the two diseases. The bones of the extremities should, however, furnish the information necessary to make a differentiation. It is important that the entire extremities be examined, including the phalanges. One of the most important points in the differentiation is found in the distal bones of the extremities. The metastases of neuroblastoma involve particularly the proximal ends of the large bones, as the humeri and femurs, and much less, if at all, the bones distal to the knees and elbows. Another disease, rare in children, that may cause cortical absorption, osteoporosis and softening and has to be considered in the differential diagnosis is hyperparathyroidism. No real difficulty should be encountered in recognizing the difference in the roentgenogram as well as the clinical and hematologic pictures between leukemia and erythroblastic anemia. The bones in erythroblastic anemia may be very porous as the result of marked hyperplasia of the marrow substances, with thinning of the cortex of the long bones, but the diffuse invasion and infiltration of the dense parts are not seen as in leukemia. A typical feature of erythroblastic anemia is the thickening of the cranial vault. What is said of erythroblastic anemia also applies to congenital hemolytic icterus and sickle cell anemia, although the changes in the latter two conditions are seldom as marked as in erythroblastic anemia.

Evaluation of Injury in Development of Hypertrophic Arthritis—In a series of extra-articular fractures of the bones of the lower legs that Doub and Jones studied they could find no evidence that a single severe trauma had any influence in producing hypertrophic arthritis. In one case that showed beginning changes about the knee joint the bowing of the femur was sufficient to alter the mechanics of the joint and thus account for the changes that were present. The authors selected cases of fracture so that they might be sure that sufficient trauma was applied to produce organic injury of surrounding structures. A single injury with hemarthrosis alone would not seem sufficient to produce permanent arthritic changes. It would seem that advancing age, with its attendant factors of arteriosclerosis and loss of elasticity and fibrillation of the

cartilage, is one of the greatest factors in the production of hypertrophic arthritis. This also includes long-standing wear and tear and minor traumas. The mechanical theory as to the etiology of hypertrophic arthritis must certainly be given a great deal of consideration. Faulty mechanics locally, as in the case of angulation of a long bone projecting the lines of force in such a way as to produce abnormal pressure on certain parts of the articular surfaces of the nearby joints may produce quite marked changes in the joint. The cartilage shows evidence of gradual erosion in the areas of abnormal pressure and this is followed by eburnation of the bone and marginal lipping. There may be anatomic changes also that produce more general changes, such as extensive scoliosis of the spine, which may not only affect the vertebrae themselves but may produce unequal strain on the peripheral joints and affect them also.

Removal of Lymph Nodes in Cancer of Cervix.—Tausig has applied to cancer of the uterine cervix the methods successfully employed by many persons in cancer of the mouth, namely, irradiation of the primary tumor and surrounding tissues and surgical resection of the tributary lymph nodes. He has attempted a combination of lymph node removal with irradiation in twenty-six group 2 and 3 (League of Nations classification) cases of cancer of the cervix. His experience with the eight more advanced group 3 cases is distinctly discouraging. On the other hand, the eighteen group 2 cases with but one primary death due to embolus and with eleven of the patients still clinically well, although five of these eleven showed cancer in the glands removed, justify the belief that this method should be given further trial. His recommendation is that only patients in good physical condition, preferably young and not obese, be selected and that the operator should be reasonably experienced in pelvic cancer surgery. With these limitations, it is fair to hope that by this method the percentage of cures in group 2 cases of cancer of the cervix may be materially increased.

Estrogenic Substance in Blood of Patients with Acne

—By means of the method of Frank and Goldberger in the determination of values for estrogenic substance in the blood of girls with acne, Rosenthal and Neustaedter obtained results that paralleled closely the earlier work on estrogenic substance in the urine determined according to the technic of Kurzrok and Ratner. This leads them to believe that associated with acne there is abnormality of formation or of utilization of the sex hormone. Although their series of cases (twenty-nine) was small, they believe that it can be assumed that a definite relationship exists and that a deficient secretion of the follicle-ripening hormone may prove to be the direct or indirect factor in the cause of one type of acne. In the course of routine filtered roentgen therapy in the treatment of acne it is conceivable that the pituitary gland is affected by the relatively low dosage of irradiation administered and in consequence induces a normal ovarian response.

Relation of Adrenals to Hypertrichosis.—On the assumption that benign adrenal hyperactivity might cause hypertrichosis without the other symptoms which occur with tumors of these glands, Niles treated twelve patients having hypertrichosis with supposedly inhibitory doses of roentgen rays to the adrenals. They received from one to nine treatments, the average number being 3.83. Some patients were given a maximal dose once a month, others, small cumulative doses three times a week, and some, both types of treatment. Although with both procedures a few patients showed a slight loss of superfluous hair after the first one or two treatments, this did not continue, and the final result was unsatisfactory in all the treated patients. In spite of these results, the author still believes that hyperactivity of the adrenals may be a factor in some cases of hypertrichosis. Failure may have been due to insufficient dosage or improper intervals between treatments, although several patients received all the radiation that was considered safe. It also may have been due to the fact that in these patients some other gland than the adrenals was at fault. He believes that the ultimate satisfactory treatment of this condition will be from the endocrine point of view.

Enlargement of One Sternoclavicular Articulation in Prenatal Syphilis.—Dorne and Zakon present the observations in a group of twelve patients demonstrating enlargement of the sternal end of the right clavicle as a sign of prenatal syphilis. These patients are all persons with recognized prenatal syphilis whom they have had under observation and treatment for varying periods and who also present other signs of prenatal syphilis. The enlargement of the sternal end of the clavicle reaches a permanent stage about the age of puberty and hence becomes a valuable permanent stigma of prenatal syphilis.

Treatment of Severe Diabetic Acidosis.—As a result of a study of eighty-six patients with diabetic acidosis, the method of treatment that Hartmann recommends includes 1 Immediate parenteral administration (one half intravenously, the remainder subcutaneously and intraperitoneally) of 60 cc. of a sixth-molar solution of racemic sodium lactate per kilogram of body weight 2 Immediate administration of 2 units of insulin per kilogram of body weight 3 Administration of 40 cc. of Ringer's solution per kilogram of body weight as soon after the administration of sodium lactate as possible 4 Repeated administration of insulin six hours later in a dose of 0.5 unit per kilogram of body weight 5 Transfusion of citrated whole blood or plasma (20 cc. per kilogram of body weight) if edema due to reduced plasma protein develops

Differential Diagnosis Between Cerebral Hemorrhage and Cerebral Thrombosis.—Aring and Merritt present an analysis of the data obtained from the records of 245 cases of cerebral vascular lesion studied clinically and at necropsy 1 Cerebral vascular accidents are rare in patients below the age of 40, but cerebral hemorrhage occurs more frequently than cerebral thrombosis in the decade from 40 to 50 2 The occurrence of a sudden severe headache or vomiting at the onset is strongly in favor of a diagnosis of cerebral hemorrhage. Convulsions are more frequent in cases of cerebral hemorrhage. The convulsions that occurred in cases of cerebral thrombosis were usually associated with syphilis or a lesion in the motor

cortex. The onset with immediate unconsciousness is more frequent in cases of cerebral hemorrhage (51 per cent) than in cases of cerebral thrombosis (32 per cent). The presence of coma on the patient's admission to the hospital is probably a more reliable index to the relative frequency of cerebral hemorrhage. Signs of progression of the cerebral vascular lesion after the onset are more frequent in cases of cerebral hemorrhage. 3 Abnormalities in the depth, rate, rhythm and sound of the respirations are more frequent in cases of cerebral hemorrhage. 4 The systolic blood pressure was greater than 200 mm in 41 per cent of the cases of cerebral hemorrhage, as compared with 26 per cent of the cases of cerebral thrombosis. Cerebral hemorrhage or cerebral thrombosis is not rare in a patient with normal blood pressure. 5 There was no evidence of arteriosclerosis in 10 per cent of the cases of cerebral hemorrhage, as compared with 1 per cent of the cases of cerebral thrombosis. 6 Abnormalities in the eyes are found more frequently in cases of cerebral hemorrhage. 7 Stiffness of the neck is usually indicative of a cerebral hemorrhage. It was found in 55 per cent of the cases of cerebral hemorrhage and in only 7 per cent of the cases of cerebral thrombosis. 8 The bilateral occurrence of the Babinski sign was noted almost twice as often in cerebral hemorrhage as in cerebral thrombosis. 9 The initial leukocyte count was markedly increased in 55 per cent of the cases of cerebral hemorrhage, as compared with 10 per cent of the cases of cerebral thrombosis without complications. 10 The cerebrospinal fluid pressure was increased in 57 per cent of the cases of cerebral hemorrhage and in 22 per cent of the cases of cerebral thrombosis. In 38 per cent of the cases of cerebral hemorrhage the cerebrospinal fluid pressure was greater than 300 mm., and in 18 per cent the pressure was greater than 400 mm. In the cases of cerebral thrombosis a pressure greater than 300 mm was rare and a pressure greater than 400 mm did not occur. A grossly bloody fluid was found in 74 per cent of the cases of cerebral hemorrhage, and it was rarely if ever found in cases of cerebral thrombosis. 11 In 50 per cent of the cases of cerebral hemorrhage the patient died within four days of the onset, and in only 28 per cent of the cases of cerebral thrombosis did the patient die in this period. Cerebral vascular lesions do not cause sudden death.

Anesthesia for Relief of Asthma.—Kahn did not secure prolonged relief in chronic intractable bronchial asthma lasting months, as was hoped for, as a result of surgical anesthesia by ether administration. The amount and the duration of relief obtained would, however, conservatively indicate that in surgical ether anesthesia the allergist possesses another weapon, at least in some instances, of decided value in breaking the recurrent asthmatic paroxysm habit of pollen etiology when other simpler measures have failed. This relief measure may have a far wider field of usefulness in intractable asthma of other etiologies, specific or nonspecific, and may also explain the correction of asthma and other hypersensitivity conditions heretofore ascribed to surgical intervention, intentional or coincidental. While ether anesthesia, both by rectum and by inhalation has undoubtedly been previously employed successfully to relieve a severe acute asthmatic paroxysm, the author believes that his three cases are the first instances of deliberately induced surgical ether anesthesia for the sole purpose of securing relief of a semipermanent character in chronic daily recurring asthma, the anesthetic being administered at the time when the patient was actually comfortable and completely or almost completely symptom free.

Bactericidal Principle in Excretions of Surgical Maggots.—Simmons obtained a potent bactericide from surgical maggots of the species *Lucilia sericata*, and the technic for its collection is described. Bactericidal tests with this substance were conducted with seven species of bacteria of etiologic importance in pyogenic infections. The results showed that exposures of from five to ten minutes were usually sufficient to give a 100 per cent kill of dense saline and broth suspensions of the organisms. The addition of organic material apparently has less effect on the potency of this material than on that of ordinary disinfectants. The active principle is of a nonviable nature and is not destroyed by autoclaving for twenty minutes.

at a pressure of 10 pounds. No indication of lysis could be demonstrated, and the thermostability and other reactions of this substance rule out the possibility of a bacteriophage as the active principle. The material was desiccated, and in this dry condition it apparently maintains its potency over a longer period than when in aqueous solution. The remarkable bactericidal potency of the excretions against *Staphylococcus aureus*, hemolytic streptococci and *Clostridium Welchii* accounts in part for the gratifying results obtained in such infections under maggot therapy. The investigation reveals a field with potentialities of producing other new and useful disinfectants from living organisms.

Disorders of the New-Born.—Bonar states that, since reduction of neonatal morbidity and mortality rates is dependent largely on the prevention or early diagnosis and treatment of disorders of the new-born by the general practitioner, his first duty is to determine the seriousness of certain symptoms promptly before the condition of the infant becomes grave. This demands a thorough physical examination and continued observation of the baby rather than delegating the entire responsibility to untrained or less competent attendants. Once the physician has found that the symptoms denote the existence of definite disease, the decision must rest with him whether or not he himself desires or has the equipment to diagnose and treat the infant. If not, the patient should be referred promptly to a capable consultant, for at no other time of life is procrastination so likely to result in an unfavorable outcome. Particularly is this true of certain infections and of a few disorders producing such common symptoms as cyanosis, vomiting and hemorrhage, for the diagnosis and treatment of which simple diagnostic and therapeutic methods applicable to practice in the home or less well equipped hospital are discussed.

Leukemia with Onset Simulating Rheumatic Disease.—Smith discusses three cases illustrating the group of children having leukemia in whom the pains in the joints are not associated with evidences of visible inflammation and clinical differentiation from rheumatic disease becomes difficult. The migratory pains in the limbs and joints are often vague, and roentgen examination of the long bones discloses no deviations from the normal. In all other respects, too, the symptomatology and physical signs resemble those cases of rheumatic disease

in childhood in which joint pains are not associated with objective signs of inflammation. The history of the three cases prior to admission to the hospital so closely resembled rheumatic fever that treatment was directed toward that condition in two. The diagnosis of lymphoid leukemia was made on the recognition of the characteristic pathologic white blood cell. Cardiac signs, when present in leukemia, may be attributed to anemia. In one case remission in fever and joint pains followed the administration of salicylates. The response to salicylate therapy may perhaps be of significance, since it may differentiate the suggestive early case of leukemia with bone and joint pains from a case of true rheumatic disease. Bone and joint pain in leukemia of childhood may perhaps be explained on an anatomic basis. At birth and for the first three or four years of life, the long bones are entirely filled with actively functioning red marrow. At about 7 years of age fat appears, which is observed grossly at puberty. The conversion of active red marrow to nonfunctioning yellow marrow is complete at 21 years of age, with the exception of residual islands of red marrow in the upper end of the proximal long bones. It is conceivable that the encroachment on actively functioning hematopoietic tissue within the inelastic bony skeleton of the child produced by the invasion and multiplication of leukoblastic cells accounts for pain in the extremities. The pain in the initial pathologic phase of leukemia is due to increased pressure within the bone caused by crowding of the multiplying cells. As the pathologic process continues, rarefaction occurs within the bone. The next step consists of the spread of leukemic cells beyond the cortex and results in an elevation of the periosteum. In the cases cited the patients did not survive beyond the stage of infiltration, so that the roentgenogram could throw no light on the pathologic process responsible for the clinical symptoms. During the period in which the diagnosis of rheumatic disease seems likely, abnormal leucocytes make their initial appearance in the circulating blood. Abnormal lymphocytes possessing distinctive microscopic features were present in the blood smear in the three cases. The cytoplasm was usually scanty and took on a deeply basophilic stain. Vacuoles were present in some cells, and in others the cytoplasm was marked by its content of coarse azure granules. The immature lymphocytes appeared in varying percentages in the peripheral blood of all cases. The diagnosis of leukemia should be considered with the recognition of these cells even when they are few in number in the differential smear. The differentiation between cells of the myeloid and lymphoid series, as well as the recognition of the identifying characteristic of the abnormal cells, was facilitated by a combination of several techniques.

Estrogenic Treatment of Gonorrheal Vaginitis.—From their observations in seventeen cases of gonorrheal vaginitis in children, Goldberg and his associates are of the opinion that short or long duration of the disease prior to the administration of amniotin is not a factor in effecting a cure. The results from the oral method do not differ materially from those by hypodermic injections. The former method would appear to be preferable because of the natural disinclination of a child to be pierced by a needle and also because of the slight danger of an associated abscess, which occurred in one of their cases. The time limit, which is an important factor in therapy, is unquestionably much shortened in effecting cures by amniotin as compared with that by the old methods. Protracted treatment is a disadvantage in any disease, particularly in pediatric practice. The recurrences after this kind of treatment are in all probability much less than with any other type of therapy. The success of the estrogenic treatment, in their opinion, depends on the conversion of the epithelial lining of the vagina from an immature type of childhood to an adult type, as demonstrated by Lewis. They are in accord with Huberman and Israeloff who believe that the acquired layer of cornified epithelial cells acts as a protective barrier against the rapidly multiplying gonococci, thus preventing reinfection. The infecting organisms that were already lodged in the subepithelial spaces have been destroyed. No ill effects and no definite change in the genitals or in the mammary glands were observed in any of these children given estrogenic substance despite the large dosage that was sometimes necessary. Possibly, injurious effects may be delayed in appearing. The last biopsies taken revealed a decided retrogression in the epithelial layers from

the adult type back toward the immature type of the vaginal epithelial tissue of childhood. In a subsequent series the authors observed enlargement of the breasts in five of eleven cases under treatment with amniotin

Analeptics as Antidotes to Pentobarbital, Chloral Hydrate and Tribrom-Ethanol—Barlow studied the effect of various analeptics in albino rabbits against lethal doses of pentobarbital, chloral hydrate and tribrom ethanol. The experimental procedures were of two types. In one maximally hypnotic doses of each agent were administered and the course of hypnosis noted. The antidotal effects of one of a series of analeptics was then determined as judged by deviations from the usual course of hypnosis. The analeptic measures tested included artificial respiration, exposure to an atmosphere containing 90 parts of oxygen and 10 parts of carbon dioxide, and medication with one of the various antidotal agents. In the other experiment the 100 per cent lethal dosage of the depressants was determined. The influence of the analeptics of definite value, as determined by the results of the first study, on the course of poisoning from lethal doses of each of the three hypnotics was then determined. Under such conditions any recoveries noted following treatment could be attributed to the effects of the analeptic measures alone. From five to ten rabbits were used in each series of experiments with each dosage of the several analeptics or other resuscitation measures. The report represents in excess of 1,600 experiments

Retention of Urine Due to Ephedrine—Valentine and Fitzgerald state that acute retention of urine due to the action of ephedrine is of significance to urologists because of the widespread use of this drug in asthma and associated conditions. They present three cases with a discussion of the probable mode of action. An attempt was later made to utilize this principle

in the treatment of "dribbling" or weak sphincteric control. In the first case a hypodermic injection caused symptoms in less than an hour. The vesical content could not have been greatly increased in this period. Severe pain with but 16 ounces (480 cc.) of urine in the bladder was noted in the second case. The third patient had pain and retentive symptoms with but 2 ounces (60 cc.) of urine in the bladder. From reported and their own observations, the authors are led to conclude that the retention will occur only in those patients who are developing prostatism or reaching the prostatic age. Red blood cells and albumin were present in all three cases and cleared on cessation of the drug. After observing the retention caused by ephedrine, the authors decided to test its value when there is need of better sphincteric control, i.e., in dribbling and in incontinence. They used it in five cases—all ambulatory. No improvement was noticed in two patients. Both were old men who were incontinent in their first two months following suprapubic prostatectomy. The internal sphincter was destroyed and the external sphincter relaxed. In another, an old man who had had perineal prostatectomy, improvement was definite, but over a long period of time. Such change was no more rapid than is frequently observed postoperatively without ephedrine. In the remaining two cases the effect was more striking. In one an internal sphincter traumatized by resection was made more tonic. Urination became more difficult, the residual increased and the dribbling ceased. In the other case the incontinence predicated on an old lesion of the central nervous system was markedly improved. The tone of the internal sphincter was increased enough to carry on its normal function.

Water Balance in Surgical Patients—Collier emphasizes that while the normal person at rest or during light activity loses from 800 to 1,500 cc of water by vaporization from the skin and lungs, the surgical patient with infection fever or hyperthyroidism or under abnormally warm environmental conditions will lose from 1,500 to 3,000 cc daily. The abnormal losses of fluid are important sources of water depletion to surgical patients. Vomiting, diarrhea drainage from intestinal and biliary fistulas or massive exudations from inflammatory surfaces such as burns, may carry away large amounts of fluid

daily. With the water loss in these instances there is also an important loss of body fluid substance. From the standpoint of water alone the losses are serious, because they carry out no physiologic purpose. If all the water losses of the body are not considered in estimations of the water requirements of surgical patients, a depletion of body fluids is likely to occur. On the basis of two clinical experiments the author has used 6 per cent of the total body weight in calculating the water requirements of the body tissues in several dehydrated patients. This estimation along with a consideration of the amount of fluid for vaporization, for abnormal losses and for a reasonable output of urine, gave him a rather exact indication of the amount of fluids needed to restore the dehydrated patient to the normal condition. The maintenance of a satisfactory water exchange is fundamentally the maintenance of a satisfactory urine output. The kidney functions with the water available after all the other channels of water excretion have been cared for. For the sick person he considers a satisfactory urine output to be about 1,500 cc a day. Normal kidneys working at a maximal concentration require close to 500 cc. of water a day to excrete an average amount of waste material. In extensive kidney disease when the concentration power has been considerably impaired, three times as much water is required to carry out the same function. The 1,500 cc volume then is ample to provide for the kidney function of practically all persons. An abundance of water can be best supplied by the use of a 5 per cent solution of dextrose. The dextrose is rapidly oxidized and the water is left available for all body needs. It is the author's custom to use sodium chloride solution for the parenteral administration of fluids only when the chemistry of the blood has shown that salt is needed. Too much salt solution may be the cause of edema.

Two Attacks of Anterior Poliomyelitis in Same Individual—Cohen points out that the immunity acquired by man as a result of one attack of anterior poliomyelitis occasionally is slow in developing. The active virus may remain in the nasopharyngeal secretion of the individual for a period up to four months following an attack, as shown by Lucas and Osgood. Therefore any relapse occurring within this period can be explained as an autoinfection of the individual by the active virus present in his own nasopharyngeal secretions, thus occurring before the full development of immunity following the first attack. This does not, of course, completely eliminate the possibility that the second attack may be a reinfection from a new external source. When the interval between the two attacks is two or more years, the reinfection is undoubtedly a new one from an external source, as the active virus has experimentally never been found to be present in the nasopharyngeal secretion of a patient later than four months after the termination of the acute febrile stage of the disease in such virulence as to reproduce the disease in a monkey. There have been no cases of a second attack reported, whether a recrudescence or a reinfection occurring in the interval between four months and two years following recovery from the first attack. Thus the author concludes that immunity to anterior poliomyelitis once it is fully developed either as a result of an attack or a recrudescence of an initial attack, is absolute only up to a period of two years. The thirteen proved cases of reinfection with anterior poliomyelitis reported in the literature are

tabulated and two new cases are cited. One of these two cases differs from all others in that there was total paralysis of two extremities and almost total paralysis of a third. Complete recovery occurred following the first attack. The three extremities that were affected as a result of the first attack were affected to practically the same degree during the course of the second attack. The fourth extremity (the left arm), which was also completely paralyzed during the course of the second attack and was not affected during the first attack, is the only one that has recovered to any appreciable degree.

Treatment of Recurrent Acute Intussusception—Miller and Beatty state that the possibility of avoiding operation in certain selected, promptly diagnosed cases of intussusception has not been sufficiently recognized. The desirability of an effective means of relieving intussusception without repeated resort to surgery is especially great in the case of individuals with recurrent attacks. They believe that it is in such cases that the nonsurgical approach of Retan and Stephens may be of the greatest value. In their case of recurrent acute intussusception, the child had one attack at the age of 20 months and a second attack nearly three months later. In both attacks the child presented the symptoms (sudden onset, intermittent abdominal cramps, prostration and collapse) and the characteristic sausage shaped tumor mass of intussusception. In neither attack had sufficient time elapsed for the passage of mucus and blood. In both attacks the diagnosis of intussusception was confirmed by a barium sulphate fluoroscopic examination within three hours of the onset and the obstruction was relieved by extra-abdominal manipulation. The use of barium sulphate enemas and massage under the fluoroscope appears to be a valuable procedure deserving a therapeutic trial in all very early cases of acute intussusception.

Analysis of Cholecystographic Observations—Johnson and Harrell employ the oral and intravenous administration of the dye in cholecystography and keep the patient in the department throughout the time consumed by the examination. The oral method was used in 189 cases, 153 of which were found to be normal. Two of these were diagnosed as poor function, and as no intravenous study was done the diagnosis remained doubtful. Cholelithiasis was demonstrated in fifteen cases by the oral method alone. A diagnosis of "pathologic gallbladder" was made in an additional nineteen cases in which the viscus failed to be filled with the dye. In four cases a negative diagnosis made by the oral route was questioned clinically but was substantiated by intravenous study. In nine cases no shadow was observed after the oral administration of the dye, only to be followed by normal observations after the dye was given intravenously. In two cases following oral dye in which the diagnosis was doubtful, a diagnosis of disease of the gallbladder could be made by the intravenous method. In one case in which the gallbladder failed to fill after oral dye there was only slight filling after the dye was given intravenously. In twenty-six cases the diagnosis of disease of the gallbladder was arrived at after the giving of dye by mouth was confirmed by intravenous study. In another case, in which a normal shadow with good function was found by the oral method, an intravenous study was doubtful. In sixty cases the referring physician requested that the examination be done by the intravenous method there being a desire for quantitative measure of liver function as well as a study of the gallbladder itself. Of these cases, thirty-five were found to be normal and twenty-eight diseased. Of the 300 patients examined, only thirty-two were operated on. In the only case in which operation was performed for possible pathologic changes of the gallbladder, despite a negative roentgen diagnosis the gallbladder was removed and the pathologist classified the condition as chronic cholecystitis. In six other cases a negative roentgen diagnosis was confirmed. In the two cases studied orally, in which there was poor filling operation revealed a diseased gallbladder in each instance. Of the oral examinations revealing stones, three patients were operated on and cholelithiasis was found in each instance. The other pathologic diagnosis made by the oral

administration in which the viscus was filled was that of obstruction due to carcinoma of the head of the pancreas. This was confirmed by operation. Of the pathologic diagnoses made by the oral method owing to nonfilling of the organ, seven patients were operated on. All were diseased, three of them containing cholesterol stones as well. In the case doubtful by the oral method and negative intravenously, a negative operative diagnosis was made. In seven of the cases studied intravenously and orally in which a pathologic roentgen diagnosis was made, the observations were confirmed at operation. The five cases in the intravenous and pathologic group in which operation was performed were found to be pathologic.

Actinomycosis and Roentgen Therapy—Fried states that there is unanimity of opinion that surgical drainage together with roentgen therapy can bring about a complete cure in actinomycosis without the administration of iodides. However, when iodides are given in large doses and for a long period of time they may also be very effective. It is generally accepted that the efficacy of irradiation in this disease is brought about by the indirect action of the rays, which alters or so modifies the tissues as to render them poor mediums for the growth of micro-organisms. Whether the changes produced in the tissues are physical, chemical or biologic is not known. Another contributing factor that aids the favorable action of the rays is the high degree of radiosensitivity of the lesions in this disorder. Because the mode of extension of the disease is more often by continuity than through the blood vessels and lymph channels, the author found it necessary to use a special technic in which the fields of irradiation extended from 2 to 5 cm beyond the palpable borders of the lesion, the rays being sufficiently penetrating to reach from 2 to 3 cm beyond the depth of the lesion. The results of the treatment in his case are satisfying because a complete cure was obtained and the patient is free from any residual keloids or disfiguring scars. Hypertrophic scars resulting from actinomycosis are covered by a thin layer of epithelium and therefore require a much smaller number of roentgen exposures than in the case of ordinary spontaneous keloids. The technic of radiation therapy in this disease apparently varies with each worker. Some use the larger initial dose method, others rely on the simple fractionated dosage, while still others administer the protracted fractionated technic.

Sugar Tolerance Test in Diagnosis of Diabetes Mellitus—Leyton presents five cases that disprove the opinion that the sugar content of the blood rising above 0.25 per cent, and remaining high for two hours, indicates diabetes mellitus. He believes that, among the patients of physicians who treat diabetes by restricted diet, a percentage of the patients treated most successfully who have never complained of thirst or polyuria belong to the category of those recorded here.

 *Demonstration of Particles of Malignant Growth in Sputum by Means of Wet Film Method L S Dudgeon and C H Wrigley—p 752

Demonstration of Particles of Malignant Growth in Sputum—Dudgeon and Wrigley have examined the sputum of fifty-eight persons believed to be suffering from malignant growth of the lung or respiratory tract. They have been able to demonstrate the histologic type of growth present in twenty out of twenty-six positive cases. They obtained the sputum as soon as it was expectorated, so as to avoid, as far as possible, both autolysis and the lesser digestive action of the polymorphonuclears. Each specimen of sputum was poured on an unglazed porcelain tile. Film preparations were then made by spreading the material with a scalpel on clean glass slides. Whenever possible, blood-streaked fragments were chosen. In the absence of these the more solid portions of sputum were used. In fixing the wet films, Schaudinn's fluid was prepared by adding one volume of absolute alcohol to two volumes of a saturated aqueous solution of mercuric chloride. The best fixation is achieved by leaving the slide immersed in the fluid for twenty minutes. When a rapid diagnosis is needed, a minimum of two minutes is all that is necessary. It is then transferred to methylated spirit to which a few drops of tincture of iodine have been added. A washing in distilled water prepares the slide for staining. Mayer's hemalum gives the most constant results as a nuclear stain. The slide is left in the stain for about two minutes or less. Deep staining should be avoided. It is then transferred to tap water. In the water the color changes from a reddish purple to blue, and the slide

must be left until "blueing" has taken place. During this time the thick or uneven parts of the film can be removed from the slide by touching them with a needle. As a counterstain a weak solution of eosin is used. The slide is then taken through the alcohols to xylene in the usual way and mounted with Canada balsam and a cover slip. It has been the authors' practice to make six preparations from each specimen of sputum, and in many cases several specimens have been taken at different dates. Particles of new growth in sputum, when fixed and stained by the foregoing method, are of two types. 1 The common form, associated with 'oat-celled' tumors. These fragments, which stain deep blue, consist of a cluster of cells that are slightly smaller than polymorphonuclear leukocytes. The individual cells may belong to one of two varieties. Cells of the first variety have no obvious cytoplasm. Their nuclei show fine granularity, a well defined eccentric nucleolus, and also that variation in density of staining so often seen in malignant tissue. The second variety of cells have a similar nucleus but also a small rim of light blue cytoplasm. Among a cluster of cells of either variety it is usually possible to find typical oat-shaped cells. 2 Fragments of either columnar or squamous celled growth. The individual cells in this group are differentiated from those of the oat-celled variety by their greater size, larger nuclei and the presence of a considerable amount of cytoplasm, which stains pink with eosin. In 68 per cent of proved cases of carcinoma of the lung or larynx it was possible to establish the diagnosis from the examination of the sputum, and in the majority of instances the microscopic type of growth present could be distinguished. A description is given of the characteristic appearances of inflammatory and "scavenger" cells, as seen in the preparations.

Combined Distance Radiation of Hypopharyngeal Cancer—Cade and Allchin's treatment of cancer of the hypopharynx deals with a method of therapy that they describe as the 'combined distance radiation.' All patients were examined by indirect laryngoscopy, the situation, extent and type of lesion were determined, oral hygiene and dental treatment precede active irradiation. Roentgenograms of the chest, neck and a barium sulfate swallow are carried out, full blood counts are done weekly. The skin of the neck and the mucous membrane of the mouth are inspected daily, a complete laryngologic examination is done weekly or twice weekly. About one third of the total number of patients treated are not hospitalized. The method of treatment consists in a combination of radiation in the following order (1) preliminary x radiation

for five days, (2) simultaneous α and gamma radiation and (3) gamma radiation with the 2 Gm radium unit continued after cessation of α -rays. The rationale underlying the combined method is based on the following observations: 1 It was pointed out by Quick that a larger tissue dose can be given with safety and comfort by the combined method than by either method alone. If the total maximal dose given by each method alone is represented by 100 per cent, allowing a reduction of 25 per cent for each type, a total dose of 150 per cent can be delivered by the combined method. 2 From the cases treated it appears that a variation of the wavelength used increases the degree of radiosensitivity. 3 The local tolerance of the skin and mucous membrane is increased. 4 The limit of general tolerance of the patient is never reached before the limit of the local tolerance of the skin or mucous membrane, so that treatment need not be interrupted before an adequate dose is delivered. The number of cases treated by the combined method during the last three and a half years was fifty-two. The longest period of survival to date is three and a half years. One patient died from other causes, free from disease by histologic examination after complete postmortem examination. Among the unsuccessful cases are those, the majority, in which initial improvement and even total disappearance of the disease was followed by local recurrence within periods varying from six to eighteen months and those in which the disease progressed in spite of and actually during the treatment. Of the fifty-two patients with hypopharyngeal cancer, seventeen remain free from disease for periods up to three and a half years.

Azotemia in Acute Nephritis.—Among ninety-eight children suffering from acute nephritis Rennie found azotemia in 60 per cent of those examined within seven days of the onset and in 51 per cent of those examined in the second week. The degree of azotemia bore no relation either to the amount of edema or to the height of the blood pressure. The nonprotein nitrogen of the blood bore no relation to the incidence or the severity of the cerebral manifestations in acute nephritis. A single observation of the nonprotein nitrogen of the blood early in the disease is of no prognostic value. The persistence of azotemia after the third week of illness was found to be of grave significance. A sufficient amount of protein in the diet does not militate against the disappearance of azotemia and has apparently no harmful effect.

*Lipiodol as Therapeutic Agent. G. Harrower—p. 715

Value of Breathing Exercises in Asthma.—Livingstone and Gillespie assert that, in seventy-five cases of asthma treated for one year with expiratory breathing exercises, good clinical results were obtained in fifty-two, improvement in twelve and no improvement in eleven cases. The improvement seemed to depend on the patient acquiring mobility of the chest, natural diaphragmatic breathing and control of the diaphragm. There is also a considerable psychologic factor. The treatment requires perseverance and effort on the part of the patient and the physician over a considerable time. A number of patients were able to abort impending attacks by these exercises, this appeared to be due to loosening and expulsion of mucus rather than to any other factor. This method of treatment is simple and applicable in all cases; it is sound treatment from the physiologic point of view. Eleven patients were unable to learn diaphragmatic control. In spite of the fact that good results are claimed from breathing exercises alone, it is held that specific treatment should not be neglected—e. g., removal of feathers or of foods—or operation in gross nasal disease.

Iodized Poppy-Seed Oil as Therapeutic Agent.—Harrower reports two cases of localized chronic inflammatory meningitis, both having a certain amount of paresis with loss of control of rectal and bladder sphincters. In both of them

iodized poppy-seed oil was injected into the cisterna magna primarily for diagnostic purposes, and the symptoms were alleviated, with complete cure later. In the author's opinion the good results of injection are due to a chemical inflammation superimposed on the chronic condition, causing absorption of the adhesions and of any blood clot or pus present with relief of the edema of the nerve roots. Lumbar or cisternal puncture is always followed by a reaction in the cerebrospinal fluid, but, judging from the almost immediate benefit in his cases, he is convinced that the iodized oil was the primary factor in producing a return to health.

Method for Determining Concentration of Urea in Blood.—Krieger used the test Patterson described for detecting gross retention of urea in the blood in more than 500 specimens of blood. The results illustrate the value of this test in indicating the presence of concentrations of urea in the blood stream above the normal range of from 20 to 40 mg. per hundred cubic centimeters. Of 170 specimens of blood in which the urea exceeded 50 mg. per hundred cubic centimeters, only six failed to give the yellow coloration. These exceptions occurred between 50 and 70 mg., of the 350 specimens with a blood urea of 50 mg. or less, ten showed a trace of color. In these ten cases the blood urea level was from 40 to 50 mg. For the rapid detection of abnormal amounts of urea, this test is without doubt of great value. With as little as 0.2 cc. of blood, gross retention of urea can be detected in a few moments.

 *Serum Accidents and Landry's Syndrome After Vaccinotherapy J. Olmer and J. Paillas—p. 236

Mental Effect of Traffic Accidents—Chavigny discusses the fear neurosis that frequently develops following an automobile or airplane accident. The neurosis frequently involves not only riding in an automobile itself but hearing a car or crossing the street. Except in persons whose occupation necessitates immediate renewal of automobile driving or airplane flying the condition is usually of favorable prognosis. The forgetting of the accident eventually leads to recovery in the majority of cases.

Landry's Syndrome After Vaccinotherapy—Olmer and Paillas describe a case in which a man, aged 35, who received three injections of a pneumococcus vaccine for a chronic bronchopneumonia, afterward developed a vaccinal reaction of serum type rapidly complicated by an acute ascending polyneuritis. The latter, after temporarily regressing, finally caused death from bulbar involvement. The authors discuss the possible pathogenesis involved and consider it probable that in this rare instance the vaccine caused a colloidoclasia, which in all respects was comparable to the disturbances produced by serotherapy.

 *Influence of Hypoglycemic State on Evolution of Bronchial Asthma J. Wegierko—p. 1379

Hypoglycemia and Bronchial Asthma—Wegierko's interest in the possible effect of hypoglycemia on bronchial asthma was aroused by a patient with diabetes whose attacks of asthma seemed to improve following the administration of insulin. In order to test this hypothesis the patient was given a large dose of insulin (30 units) in a fasting state and while suffering from an asthmatic attack. The asthma subsided during the development of the resultant hypoglycemia, and the patient remained free from asthma for two succeeding months. A further group of twelve patients with asthma was given insulin during an asthmatic attack to produce hypoglycemia. In all instances the asthmatic attacks subsided with the appearance of hypoglycemia. In some instances, however, they reappeared with the return of normal glycemia. No conclusions can be drawn regarding the possible therapeutic role of artificially produced hypoglycemia in asthma, but attention is merely directed toward the curious fact.

 *Value of Xanthoproteic Reaction in Diagnosis of Renal Insufficiency N. O. Irdelp, M. Guehan and Mlle. Mufide Kazim—p. 1396

Xanthoproteic Reaction in Renal Insufficiency—Irdelp and his co-workers investigated the xanthoproteic reaction in renal insufficiency with parallel blood urea determinations. The technic of the reaction is simple. The plasma or blood is dealbuminized by the addition of an equal quantity of 20 per cent trichloroacetic acid. To 2 cc. of the filtrate placed in a test tube 0.5 cc. of concentrated nitric acid is added. After shaking, the mixture is heated, without boiling, for half a minute over a flame. After cooling, 1.5 cc. of a 33 per cent solution of sodium hydroxide is added and the volume adjusted to 4 cc. with the addition of distilled water. After ten minutes, the yellow liquid is placed in an Autenricht colorimeter and the color matched. The normal value lies between 15 and 35 (usually around 20) but is raised in certain pathologic states. The authors made these determinations in 128 cases of acute, subacute and chronic nephritis. Also the blood urea was determined in all instances and the indicanemia in a large number of cases. The value of the xanthoproteic reaction was raised in all cases of renal insufficiency and was parallel with the blood urea and especially the indicanemia. The authors conclude that the reaction is indisputably valuable in the diagnosis and prognosis of renal insufficiency and may prove an important supplement to the information furnished by measurement of the blood urea.

Analgesic Effects of Bee Venom in Cancer of Female Genitalia—Natale observed the analgesic effects of bee and wasp venom in forty-eight cases of cancer of the female genitalia. He injected subcutaneously a first solution containing 0.00001 Gm. of bee venom per cubic centimeter and a second solution containing 0.00003 Gm. of venom per cubic centimeter. The wasp venom was administered in solutions of the same concentrations. The author started with small daily doses of from 0.2 to 0.5 cc. of the first venom solution. These were gradually increased to 2 cc. by the time the second solution was administered. The injections were given every day until the maximal effect was obtained. Of twenty-six patients treated with bee venom, eight obtained no relief, four showed temporary diminution of pain and fourteen showed complete relief. Treatment was well tolerated by all patients. Only cases of mild pain responded to treatment. Those with moderate or intense pain evinced no improvement. The duration of the sedative effect varied. An injection of from 2 to 3 cc. of the second solution of bee venom generally abolished the pain for twenty-four hours. In some cases the sedative effect did not last more than a few hours, while in others the pain disappeared for from several to eight days, and permanently in six cases. The analgesic action is seldom accompanied by disturbances, such as nausea and vomiting, which frequently result from the usual sedatives. The maximal arterial pressure is generally lowered by about 10 mm. of mercury. The effects of wasp venom treatment as a rule correspond to those obtained with bee venom. The wasp venom, however, may cause mild pains in the beginning. Of twenty-two cases treated with wasp venom, four patients presenting mild pain and four others with severe pain obtained no relief. In fourteen cases the pains disappeared by the third or fourth day. The results obtained with wasp venom were less marked than those obtained with bee venom, but they lasted longer. The analgesic action of wasp venom continued for a few days, generally from three to four but sometimes for as many as thirteen days. Neither venom produced local reaction or vomiting or nausea. Lipothymia was not observed after administration of wasp venom as it was in several patients after administration of bee venom. The hypotensive action of the wasp venom did not differ from that of the bee venom. Fifteen minutes after injection there was a gradual fall in the arterial pressure to from 5 to 10 mm. of mercury.

Patiño Mayer's Signs of Syphilis—Pataro states that lymphocytosis, with more than 30 per cent lymphocytes in the blood and when associated with a clinical picture of suggested syphilis, is of value in the diagnosis of syphilis except in febrile or infectious diseases in which lymphocytosis is a characteristic of the disease. In primary syphilis, lymphocytosis appears when the ganglionic reaction begins to develop, that is, about one week after appearance of the initial chancre. In secondary, tertiary and congenital syphilis, lymphocytosis exists with a positive Wassermann reaction or with a negative Wassermann

reaction that turns positive a few days later. Syphilitic lymphocytosis increases when antisyphilitic treatment is begun (reactivation) but decreases and remains stationary with more than 30 per cent lymphocytes in the blood of patients who have had sufficient treatment and intensifies itself in patients who have not. The author gives Patiño Mayer credit for discovering these signs. He calls "Patiño sign" the primary lymphocytosis, and "tattooing of the blood by lymphocytosis, described by Patiño," the persistence or intensification of lymphocytosis after treatment.

Pure Glucoside of Squill (Scilla Maritima) in Treatment of Cardiac Disturbances F Bach and A Berr—p 1591

Significance of Kauffmann's Diuresis Test—Rubbaum and Gemeinhardt made the Kauffmann diuresis test on three groups of persons: healthy ones, patients with compensated heart disease and patients with a slight degree of decompensation. On the basis of suggestions in the literature and of their own observations, they modified the test in some points so that it differed slightly from Kauffmann's original test. In none of the tested groups did they find that Kauffmann's diuresis test was a suitable diagnostic aid. The outcome of the parallel tests without elevation of the legs corroborated these results. The authors discuss a number of factors in Kauffmann's test that may be sources of error.

Disturbances of Peripheral Blood Perfusion—Under the collective term disturbances of peripheral blood perfusion Ratschow designates a group of vascular diseases the most important symptoms of which are disorders of the extremities of the organism (hands, feet, nose, ears). However, the local restriction of these disorders is only apparent, for the disease processes usually involve the entire vascular system. For this reason it seemed desirable to look for signs that would permit an estimation of vascular regions that are not directly within the sphere of the diseased tissues. A changed behavior of the blood pressure would seem likely, but the blood pressure is practically normal in the majority of patients with disturbances in the peripheral blood perfusion. However, in some patients with Buerger's disease a constant increase in blood pressure has been observed, the author himself observing two such cases. In this connection he points out that recent studies by Förster and others revealed that Buerger's disease may be the cause of multiple sclerosis, transverse myelitis and other neurologic disorders. He concludes that, particularly in younger persons, hypertension of unknown origin would suggest the possibility of obliterating endarteritis. In patients with Raynaud's disease, the typical attacks are occasionally accompanied by attacks of hypertension. It is assumed that, if hypertension is present during the attack, the disease process involves vascular regions of internal organs. The author points out that the determination of the fluctuations in the blood pressure which develop in response to tolerance tests on the peripheral circulation gives more information than does the ordinary determination of the blood pressure. There are two ways of doing this: (1) The local pressure can be registered by means of the recording sphygmomanometer of Tvcos and (2) the modification of the blood pressure by the stasis experiment of Hertzell can be determined. In employing Hertzell's stasis experiment the author observed the greatest deviations from the normal curve in patients in whom the larger peripheral vessels had become stenosed or occluded. In thirty-four patients with arteriosclerosis without hypertension he was able to corroborate Lange's observation that the increase in blood pressure is absent after stasis, whereas in arteriosclerosis with hypertension the increase in blood pressure was greater than in normal persons. In arteriosclerotic diabetic gangrene the blood pressure curves corresponded with those of uncomplicated arteriosclerosis as a proof that peripheral gangrene alone does not permit conclusions regarding the condition of the larger vessels. There were also cases of Buerger's disease with gangrenous processes of the toes in which the functional tests indicated that larger vessels

were relatively unimpaired. Patients with acrocyanosis often showed considerable fluctuations in the increase and decrease but otherwise showed a normal behavior. Patients with Raynaud's disease had normal blood pressure changes outside of the attacks, whereas during the attacks the stasis experiment did not elicit fluctuations.

Behavior of Cevitamic Acid in Immunized Animals—Jusatz and his associates determined that prolonged feeding with a diet deficient in vitamin C results in a reduction of the cevitamic acid as well as of the glutathione in the adrenals. The artificial administration of vitamin C prevents this and again produces an increase in these two reducing substances in the adrenals of animals that have received a vitamin deficient diet. Thus there seems to be a close relationship between glutathione and cevitamic acid in the adrenals. The simultaneous occurrence of these two reducing substances in the adrenals is doubtless of functional importance. The authors observed that glutathione exerts a protective action on cevitamic acid. In the experiments described in this report, the authors aimed at determining the behavior of these two reducing substances in immunized animals, because former observations of one of the authors had indicated that an adequate supply of vitamin C is necessary for the development and maintenance of immunity. The blood of animals that for several months have been deprived of vitamin C has only a slight bactericidal power, and the capacity to form antibodies is reduced and retarded. If these animals are given vitamin C in the form of cevitamic acid, the bactericidal power of the blood and the antibody formation are increased. After immunization with horse serum, the glutathione content of the blood of rabbits is reduced. In animals that for several months had been fed on rations deficient in vitamin C and were then immunized, the adrenals contained smaller amounts of cevitamic acid and of glutathione than did those of the animals that had not been immunized. This indicates that cevitamic acid and glutathione are consumed in the course of antibody formation that takes place in immunization with horse serum. If a vitamin deficient diet accompanies antibody formation, the supply of these substances in the adrenals becomes exhausted.

Action of Magnesium on Heart—Zwillinger reports the history of a patient who had chronic bronchitis, emphysema, cardiac myodegeneration and a severe decompensation. Treatment with digitalis had been given for some time but this medication had to be interrupted on account of toxic manifestations. However, several days after the interruption of the digitalis therapy it became necessary to aid the circulation with strophanthin, but soon there developed extrasystoles and then paroxysms, ventricular flutters and fibrillations. These attacks of flutters and fibrillations were accompanied by cyanosis and cessation of pulsation and of the respiration, but they were of only short duration. Between the attacks there existed extrasystolic arrhythmia. Quinidine was without effect. In the course of an especially severe and prolonged attack of ventricular flutter, when even the corneal reflexes had been abolished and a spontaneous recovery was not expected the patient was given for the first time an intracardial injection of 10 cc of a 15 per cent solution of magnesium sulfate. After a few seconds, consciousness returned. The attack of fibrillation was interrupted and there followed a few extrasystoles but soon the sinus rhythm was undisturbed. Later attacks of extrasystolic arrhythmia could again be interrupted by injections of magnesium sulfate. The patient, who died as the result of a bronchopneumonia, had an uninterrupted sinus rhythm before death. The observations on this patient induced the author to further studies on the action of magnesium. He tried magnesium sulfate in a number of patients with extrasystole or

tachycardia. In all cases the effect was prompt. The extrasystoles, no matter of what origin, disappeared within a few seconds, but this effect persisted at the most for three hours. The author states that it is advisable to inject first 4 cc. of a 10 per cent solution of magnesium sulfate as a sensitivity test. In extrasystoles he employs from 10 to 20 cc. of the 15 per cent solution. The injection of magnesium sulfate was tried also in three cases of prolonged auricular flutter and in two cases of auricular fibrillation but was ineffective, while it proved effective in a case of strophanthin intoxication. The author made experiments on rabbits in order to determine the effect of magnesium sulfate on strophanthin or digitalis intoxication. Observations made so far indicate clearly that it exerts an influence on digitalis and strophanthin intoxication.

New Methods for Staining Blood—Hirschfeld first describes a simple oxydase reaction which requires only two reagents that are available in any laboratory, namely, strong solution of iodine and methylene blue. He puts about ten drops of the iodine into a small watch glass. A drop of water, the size of a pinhead, is placed in the center of a cover glass that fits over the watch glass. The clean side of a thin cover glass, on which blood has been spread but not fixed, is pressed onto the drop of water to make the two cover glasses adhere. Then the cover glasses with the blood downward are placed over the watch glass. The developing iodine vapors fix the spread. This requires five minutes on the average, but a slightly longer time is necessary if the room temperature is low, and a shorter time is sufficient in case of high temperature. The cover glass is carefully removed and is stained for five minutes with Löffler's methylene blue. Then follows washing with a strong water stream and the cover glass is dried by means of blotting paper. The preparations should now have a brownish color. Then follows mounting with Canada balsam. After describing the appearance of the various blood elements if this method is used, the author points out that if the preparations are stained too much so that the granules appear black a new preparation must be made and the time of exposure to the iodine vapors must be shortened. If, on the other hand, the staining is too weak, the exposure to iodine must be prolonged. The second staining method described by the author is the staining of the granulophilytes in the dry preparation. In this test it is necessary to make extremely thin spreads so as to have the erythrocytes in a single layer. Löffler's methylene blue is poured over an unfixed spread and is allowed to act on it for about five minutes. Then the stain is poured off and water is carefully dropped on the slide to wash the stain. Whereas otherwise there results complete hemolysis from the use of watery solutions, Löffler's methylene blue solution extracts only the hemoglobin and leaves the stroma of the erythrocytes visible, so that in many the granulofilamentous substance is recognizable. However, as yet the stromas are too pale to make counting easy. To bring them out more clearly the slides are set up aslant and left to dry in the air. Then they are either passed through a flame five times or are fixed for three minutes in methyl alcohol. Then they are put for two minutes into a half diluted Manson's solution (borax-methylene blue) or, still better, into carbolated gentian violet. After careful rinsing and drying there follows mounting with Canada balsam. In these preparations the erythrocytes are quite clear and the granulophilytes have a clear blue-violet color. To be sure, the granules and the stromas are not quite as clear as in the case of supravitral methods, but they are clear enough to permit the determination of the percentages. Even the leukocytes can be counted by one who has sufficient experience.

*Significance of Mobile Fetal Head Above Pelvic Inlet in Primiparas. J. Farkas —p. 138

*Interstitial Form of Tubal Pregnancy. P. N. Logwinsky —p. 144

Fetal Head Above Pelvic Inlet in Primiparas—Farkas studied the obstetric material of the institute for midwifery in Budapest with regard to the degree of engagement of the fetal

head. He reaches the conclusion that the "floating" head signifies in primiparas not always a disproportion between the child and the pelvis. He found that in a total number of 3,829 primiparas there were 305 (8 per cent) in whom the head was floating. The pelvis was contracted in fifty of these but was normal in the others. Delivery was spontaneous in more than 87 per cent of these cases. The author thinks that the condition of the abdominal walls and the uterine contractions do not play an important part in the retarded engagement of the fetal head, but that an increased resistance on the part of the lower portion of the uterus is the chief cause. Since the necessity of a surgical intervention is possible in these cases, he thinks that delivery should be done in an obstetric institution.

Interstitial Pregnancy—Logwinsky points out that, according to the localization and the direction of the growth of the ovum, various classifications have been suggested for interstitial pregnancy. Glaesmer classifies interstitial pregnancy according to the direction in which the ovum develops into three types: (1) growth in the direction of the isthmus, (2) growth in the musculature of the fundus uteri and (3) growth in the lateral wall of the uterus. After citing figures on the frequency of interstitial pregnancy the author points out that the etiology of this and of other forms of ectopic pregnancies is not fully understood as yet, but, on the basis of reports in the literature and of his own observations, he thinks that inflammatory changes in the tubes play the most important part. The diagnosis of interstitial pregnancy is rather difficult. Asymmetry of the uterus is not a definite proof, because this is present also in the early stages of angular pregnancy. To be sure, the uterus becomes spherical if the growing ovum begins to fill the uterine cavity, whereas the asymmetry increases constantly in interstitial pregnancy. Some authors ascribe considerable importance to the Simon-Ruge sign, that is, to the fact that the upper boundary of the fundus uteri becomes oblique as the result of the hypertrophy of one of its angles. However, according to Glaesmer, this sign develops only if the ovum grows in the musculature of the fundus uteri but is absent if the growth progresses in the direction of the isthmus or of the lateral uterine wall. Other signs that have been cited as indicative of interstitial pregnancy are the wide base of the uterus and the displacement of the round ligament. Interstitial pregnancy results nearly always in rupture and usually is accompanied by threatening hemorrhages. For this reason early diagnosis is important for the best treatment is early surgical intervention. The author considers the wedge-shaped resection of the pregnant angle of the uterus the method of choice, because it does not make impossible further conception and normal delivery. He performed this operation in the two cases of interstitial pregnancy described by him. However, in cases in which the fetal sac has already damaged the uterine wall, supravaginal amputation of the uterus is necessary.

*Ten Years' Autohemotherapy of Pneumonia. G. Tillmann —p. 1604

Ten Years' Autohemotherapy of Pneumonia—Tillmann calls attention to the various quinine preparations that have been recommended for the treatment of pneumonia. He evaluates the monovalent and the polyvalent serums, pointing out that they are rather expensive that valuable time is lost in their preparation that the administration of large amounts of serum involves dangers and that the results obtained with the specific serums have not been noticeably better than those produced with other methods. He himself obtained better results with autohemotherapy than with any other method. He gives a brief description of a case treated in 1925, in which he first observed the favorable effect of autohemotherapy. In the course of the last eight years he has resorted to it in 100 cases of true pneumonia and in sixty-five cases of postoperative pneumonia. The youngest patient was 4 months old and the oldest 77 years. The author asserts that any one who has seen the pronounced changes produced by autohemotherapy in severe cases of pneu-

monia may be convinced that it is a causal treatment. He observed that the earlier in the course of the pneumonia the autohemotherapy is begun, the more rapid is the success. The technic is simple, but it is best done by two persons: the physician withdraws the blood from the vein and the assistant injects it into the thigh. From 50 to 60 cc. of blood is usually employed in adults, but it is best to use syringes of not more than 10 cc. capacity. It is advisable to inject the blood from one opening in several directions. In nurslings in whom only 5 cc. of blood is required, it may be withdrawn from the cervical vein. The author concludes that autohemotherapy, if applied early, is the best method for uncomplicated pneumonia.

Aspects of Urinary Melanogen.—Fürth and Friedrich call attention to their previous studies on the elimination of melanogen in the urine in case of melanosis and report further studies. They used a simple method of conservation of the urine, which long ago was recommended by von Zeynek. The authors thought that it might prove possible to effect a precipitation of melanogen from the urine saturated with barium hydroxide by means of mercury acetate. When to 50 cc. of the mixed melanogen urine saturated with barium hydroxide there were added 10 cc. of glacial acetic acid and then 20 cc. of a saturated aqueous solution of mercury acetate, a voluminous coarsely flocculated precipitate developed, which contained all the melanogen. This precipitate was immediately filtered off, carefully washed with water and dried at room temperature in the vacuum above concentrated sulphuric acid. They produced melanin from the melanogen of the urine by means of oxidation with iron chloride and report the results of the analysis of the melanin, carbon-hydrogen, nitrogen sulphur and chlorine contents. Finally they describe experiments on the artificial production of melanogenuria in rabbits.

Criticism of Serochemical Diagnosis of Carcinoma.—Epstein calls attention to a serochemical method for the early diagnosis of carcinoma, devised by Links. The favorable estimation of Links' test by several other investigators who employed it induced the author to try the method. He reached the conclusion that Links' formula cannot serve as a basis for a serodiagnosis of carcinoma. The essential part of the formula, the product of the potassium and magnesium factors, proves, in the majority of cases, without significance for the correctness of the diagnosis, whereas the Sahli factor indicates merely the anemic condition.

- Foreign Body in Renal Pelvis. R. Chwalla—p. 1210
- *Spontaneous Cure of Multiple Pulmonary Echinococcus. V. Stern—p. 1211

Habituation to Use of Insulin.—In studies on the course of forced feeding cures with insulin, Mainzer and Joel noted that during intravenous administration of insulin the descending portion of the blood sugar curve of persons who are habituated to insulin does not differ from that of the normal curve but returns more rapidly to the initial level and has a tendency to a hyperglycemic reaction. This is the result of a hypophyseally conditioned counterregulation of the adrenals. This observation explained that in the insulin-habituated diabetic patient sudden abstinence from insulin may result in a complete breakdown of the carbohydrate metabolism and also that following a forced feeding treatment with insulin, a diabetes like disturbance can be observed following a sugar tolerance test. That the reduction of the blood sugar is more rapid in the case of intravenous administration of insulin than in the case of subcutaneous administration is understandable. However, that this

reduction in the latter case is slower in the insulin-habituated organism than in the normal organism requires an explanation. In view of the sudden action of the intravenously administered insulin, there is no possibility for a counterregulation during the phase of reduction in the blood sugar content. Thus there are, in spite of the different degrees of counterregulation in the insulin-habituated and in the normal organism, practically identical curves of the reduction phase. The onset of the counterregulation coincides under these conditions with the exhaustion of the insulin effect. It is different in the case of subcutaneous administration, in which the resorption is slower and the insulin effect persists twice as long or longer. If therefore the counterregulation begins at the same time as in the case of the intravenous test, its influence must become evident in the descending branch of the blood sugar curve. In accordance with this, the blood sugar decreases more slowly and less deeply in the insulin-habituated than in the normal organism. Another cause for the inhibited hypoglycemia in the insulin-habituated organism is the initial 'insulin hyperglycemia' that develops even in the case of subcutaneous administration of insulin. The author describes observations in a case of acromegaly which indicate that the counterregulation is effected by the hypophysis and partly without the intermediate action of the adrenals.

Spontaneous Cure of Pulmonary Echinococcus.—Stern discusses the diagnosis of pulmonary echinococcus, pointing out that the diagnosis is not difficult with the aid of roentgenologic and intradermal examinations. He mentions the roentgenologic aspects and enumerates the disorders that must be considered in the differential diagnosis. He stresses that roentgenoscopy alone cannot be the basis of the diagnosis but that the anamnesis and clinical and laboratory examinations also must be considered. He states that, although most of these factors have been discussed in previous reports, little is as yet known about the roentgenologic aspects of the spontaneous cure of pulmonary echinococcus cysts. He differentiates two forms of spontaneous cure: (1) the perforation of the cyst into a bronchus and (2) the calcification of a cyst. The spontaneous cure of multiple pulmonary echinococcus can take place according to the first, the second or the mixed type. The author reports the history of a man aged 30, whose anamnesis revealed that for a while he had had attacks of coughing with expectoration of numerous membranous shreds. He discusses the differential diagnosis and points out that this case fills in a gap in the roentgenologic aspects of pulmonary echinococcus in that it reveals the various stages of development of the echinococcus cyst. Moreover, it refutes the statement of Grossmann, who maintained that a spontaneous cure was impossible in case of a multiple pulmonary echinococcus and it contradicts Axelrod, who denied the possibility of the calcification of a dead echinococcus cyst. The roentgenologic aspects of this case corroborated the importance of Steiner's symptom, namely the double contour or the shadow of the echinococcus cyst. Another noteworthy aspect of this case is that both types of spontaneous cure took place, perforation into the bronchus and calcification of a dead cyst.

- *Local Healing of Ureteral Fistulas and Its Therapeutic Promotion. W. Stoeckel—p. 2347
- *Pregnancy Pyelitis and Ileus as So-Called Toxicosis. Focal Allergy During Pregnancy. G. von Bud—p. 2355
- Late Results of Pregnancy Pyelitis. H. Jacoby—p. 2364
- Renal Calculi and Pregnancy. G. Tzschupolopoulos—p. 2366

Local Healing of Ureteral Fistulas.—Stoeckel says that it has long been known that ureteral fistulas frequently heal spontaneously and that many surgeons are of the opinion that spontaneous cure should be waited for. The author concedes that the spontaneous healing is always a symptomatic success for it means liberation from a painful and disagreeable disorder. However, from the functional point of view, spontaneous healing is frequently not a success: it is not desirable if the kidney to which the fistulous ureter belongs has become excluded as the result of ureteral obliteration or has become severely infected, or if these two conditions coexist. The author shows that, if preservation and functional restoration of the 'fistulous' kidney is demanded and aimed at, it must be understood that

spontaneous healing is possible only in case of incomplete fistulas and not even in all these cases, and that it is always impossible in case of complete fistulas. He illustrates this with diagrams and emphasizes that a complete ureterovaginal fistula can heal only by way of obliteration of the ureter, that is, with exclusion of the pertaining kidney. Thus spontaneous cure in such cases is equivalent to nephrectomy and should be replaced by early vesical implantation of the fistulous ureter. In some incomplete fistulas, the kidney can be saved. If in case of incomplete fistula the ureter is bent, much depends on how the ureteral peristalsis influences the angle in the ureter, for if it intensifies the angle it prevents healing, but if it stretches the angle it promotes healing. The treatment should aim at stretching the site of the fistula. An attempt should be made to bridge and to immobilize the site of the fistula by means of a retaining ureteral catheter. The author designates such a procedure as "active waiting."

Pregnancy Pyelitis (Ileus) as Toxicosis Focal Allergy During Pregnancy—Von Bud states that he treated twenty-five cases of pregnancy pyelitis. Observations convinced him of the importance of focal infection and of the therapeutic value of the elimination of the infectious foci. He also observed that pyelitis is preceded or followed by subcutaneous suffusions, pyoderms, dermatoses, subicterus, anemias, renal and biliary calculi, colpitudes, hydramnion, edemas and atony of the uterus. The puerperal pyelitis are to be regarded as flare-ups. Pregnancy pyelitis often results in abortion, premature birth or congenital disorders in the fetus, such as skin diseases and congenital icterus. Severe pyelitis of pregnancy may result in the death of the mother from uremia, sepsis or so called toxicosis. The author shows further that pyelitis of pregnancy may become complicated by pregnancy ileus. In discussing the etiology of pyelitis and ileus of pregnancy, he expresses the opinion that they are systemic disorders and that stasis and infection are promoting and eliciting factors but not causes. He is inclined to think that these disorders of pregnancy develop on the basis of a focal allergy and shows that pregnancy pyelitis may be regarded as a "dermatosis" of the renal pelvis. He regards cystic mole and chorionepithelioma as a skin disease of the trophoblast of the young ovum. He shows that the elimination of the foci of infection before, during or after pregnancy has a desensitizing effect.

Vaccine Therapy of Whooping Cough—Kandyba and Geyler report the results of bacterial vaccine therapy in 142 children ranging in age from 4 months to 12 years, suffering from whooping cough. The vaccine was of the concentration of 4 billion microbes to 1 cc. The total amount injected in the course of treatment divided in five or six injections with intervals of one or two days amounted to from 20 to 24 billion microbes. The authors conclude that the bacterial vaccine therapy of whooping cough manifests signs of specificity and gives satisfactory results, although it does not, as a rule, succeed in aborting the course of the disease. The therapeutic effect manifests itself in the diminution of the number and the severity of coughing spasms and in the abatement or termination of vomiting. The duration of the disease is shortened. The earlier the vaccine therapy is instituted, the better the results. In order to obtain a therapeutic effect, the treatment should be instituted not later than the eleventh or twelfth day of the disease. Vaccination begun after the nineteenth day was as a rule without effect. Vaccine therapy did not exert any influence on the course of intercurrent complications of whooping cough. The existence of pneumonia is no contraindication to vaccine therapy. Local reaction was observed in 70 per cent and general in 30 per cent of the cases. The authors conclude that the vaccine therapy is a harmless method.

Hemorrhages in Course of Diabetes Mellitus—Lips reports a case of diabetes mellitus in a youth, aged 16. The patient exhibited occasionally hematuria while receiving a daily administration of insulin. Omission of insulin one day caused the patient to feel thirsty and dizzy and it led to repeated vomiting of stomach contents mixed with blood. A state of coma supervened from which the patient recovered on carefully regulated insulin treatment. From the review of the literature and his own case, the author arrives at the conclusion that hemorrhages in the course of diabetes treated by insulin are not caused by insulin but are due to the toxic changes in the blood vessels. Insulin or, when insulin is not administered, trauma, embolism or thrombosis should be considered only contributing factors.

Course and Therapy of Diabetes Mellitus in Children C W Herlitz.

—p 166

*Treatment of Diabetes Mellitus During Childhood Without Dietetic Restrictions B Söderling—p 1-41

Treatment of Diabetes Mellitus—Söderling shows that in recent years a number of investigators have demanded a diet with a greater carbohydrate content for patients with diabetes mellitus. He himself has prescribed an entirely unrestricted diet for twenty-one diabetic patients, aged between 3 and 34 years, reasoning that the incretory deficiency is satisfactorily compensated by insulin. The patients have been under observation from six to thirty months. The author adhered to three guiding principles. 1 The well being of the patient is of primary importance. At each control attention was paid to his weight, working capacity, mood, polydipsia and polyuria. 2 The urine must be free from acetone, that is, Legal's test must be entirely negative. 3 Insulin is administered in such a manner that hypoglycemia and an abrupt decrease in the curve are avoided. The patients were put on an ordinary home diet and even sugar and sweet desserts were taken. This treatment was highly satisfactory in that the patients were able to lead active lives, felt well and had a considerable margin of safety against infections, acidosis and insulin reactions. In sixteen renewed hospitalization proved unnecessary, and precoma or coma did not develop in any of the patients. The insulin dosage, the consumption of carbohydrates, the sugar content of blood and urine and the physical development are discussed. The author stresses that he observed no impairment of the insulin apparatus as the result of the free diet. In two cases the insulin requirement had increased after a year, whereas it was surprisingly constant in the majority of cases. Of seventeen patients of an earlier date, nine continued to receive the same amount of insulin, four were given a larger dose and four a smaller dose after the diet was changed from a restricted one to a free one. The physical and sexual development progressed normally in the course of this treatment.

*Synthetic Androsterone Preliminary Experiences with Its Effect on Seminal Vesicles in Castrated Male Rats E. Jacobsen and J T Christensen—p 319

Investigations on Hyperlipemia and Cholesteroluria J Bing and U Starup—p 332

Synthetic Androsterone—Jacobsen and Christensen report that a compound prepared from cholesterol, made according to the method of Ruzicka and chemically identical with Butenandt's androsterone, exerted a distinct effect on the growth of the seminal vesicles in castrated rats, the necessary dosage depending on the age of the animals and the length of time since castration. A strong regeneration resulted from a daily dose of 3 mg. 1 mg daily when administered immediately after castration, to a certain extent prevented castration atrophy.

THE MODERN TREATMENT OF SURGICAL SHOCK

CHARLES H. FRAZIER, M.D., Sc.D.

John Rhea Barton Professor of Surgery University of Pennsylvania School of Medicine
PHILADELPHIA

The subject of traumatic shock is perennial, like our poor relations it is always with us. It has provided a veritable storehouse of controversy. Theories as to the causation of shock as advanced even today and championed so vigorously are such that many of the papers on this subject have the tenor of a debating society about them. And yet the condition we know as shock was known to the ancients although not designated by this term until 1795, when James Latta¹ so termed it. In dealing with a subject on which so much thought and experimentation have been expended, it is of particular interest to look back a few years to find out what was known of the subject a generation ago. Fifty years ago that peer of surgeons D. Hayes Agnew² discussed shock, and many of his observations appear quite modern. The symptoms associated with shock as observed by Agnew are much the same as they are known today. Agnew defined shock as a "term used to express the collective phenomena which follows the infliction of some violence to the body through the nervous system." The causes of shock were classified as psychical and physical.

Just how much actual shock can be produced by psychic trauma is difficult to say but every physician has seen patients who have responded to an apparent psychic injury by the symptoms of mild primary shock. I recall the case of a sturdy man who came to the operating room with his blood pressure so low that operation had to be deferred and restoratives given. Later I found the cause of his dilemma. A substitute orderly had prepared him for operation, and in the conversation that ensued the patient was told by the orderly that he was going to have an operation from which he had seen no one recover.

Shock was expected in Agnew's day, just as it is today, to follow severe physical trauma. For the treatment of shock Agnew advised placing the patient in the recumbent position with the head low, with the application of external heat and blood transfusion if there had been loss of blood. In cases in which there was engorgement of the right side of the heart, bleeding was to be resorted to. Stimulants were to be carefully given brandy and whisky by mouth, subcutaneously or by rectum.

But the concept of the mechanism of shock has been changed since Agnew's day. Agnew quotes Mitchell, Keen and Moorehouse, who made their observations during the Civil War and who felt that the medulla and the pneumogastric nerve were chiefly concerned in initiating the condition of shock, but he himself felt that the central factor in shock was more widespread. Agnew accounted for the pooling of blood in the "deep venous trunks by associating together feebleness of the heart and paralysis of the walls of the blood vessels." He did not hit far amiss of the mark. The fall in temperature Agnew explained on the basis of a temporary arrest of tissue metamorphosis. Today, in spite of the more accurate data concerning the state of the organism, during the condition termed shock there is no unanimity of opinion as regards the actual mechanism of the initiation of the condition.

I shall review hastily some of the various theories regarding the cause of shock. Crile's³ theory that the marked physiologic and nervous depression associated with shock is the result of exhaustion of the vital nerve centers received widespread attention until it was shown by Forbes and his co-workers that the changes in the central nervous system were the result and not the cause of shock. In addition, Dolley,⁴ Janeway and Ewing⁵ and Cannon⁶ produced evidence to discount this theory. Notwithstanding the mass of evidence against this theory, it is occasionally reviewed. O'Shaughnessy and Slome⁷ in January 1935 published data on experiments on traumatic shock and discussed their data in relation to Crile's³ theory.

For a time Yandell Henderson's⁸ theory held a prominent place in all discussions on shock. Henderson believed that the loss of carbon dioxide from the body was the initiating factor in shock, closely allied with this view was the question as to whether or not acidosis might be the factor of prime importance in shock. The effect of the loss of carbon dioxide by hyperventilation and its relation to shock was studied also by Janeway and Ewing,⁵ and Mann⁹ studied the effects of a possible loss of carbon dioxide through the opened abdomen. But experiments indicate that the loss of carbon dioxide is not the cause of shock. As regards the relation of acidosis to the cause of shock, the experiments of the Medical Research Committee¹⁰ showed that a marked acidosis could be produced by the injection of acid without producing shock.

Following the work of Dale, Laidlaw and Richards¹¹ on the relationship between histamine and shock, a theory was advanced that shock was caused by the liberation of toxic substances generated at the site of the injury. Histamine or histamine-like substances were known to occur in injured tissues, and varying degrees of a shocklike state could be produced by the injection of histamine. Cannon and Bayliss¹² found that when a cat's thigh was traumatized shock did not result if the blood supply to the extremity was excluded, even though the nerve supply to the limb was intact. That toxemia *per se* was not the cause of shock was suggested by the work of Parsons and Phemister,¹³ who injected the blood drawn from the femoral veins of the traumatized limb of dogs and reinjected this material into normal animals without producing shock.

Recently Freeman¹⁴ has postulated that the phenomena of shock may be explained on the basis of hyperactivity of the sympathetic-adrenal system. By the repeated injections of epinephrine he was able to reduce the blood volume in animals, a fact previously established by Gasser, Erlanger and Meek.¹⁵ In addition, Freeman¹⁴ caused a reduction in blood volume by the initiation of "sham rage" in cats in which the cerebral cortex had been destroyed. With associated paralysis of vasoconstrictor fibers by ergotoxine or after a complete sympathectomy, injections of epinephrine or "sham rage" did not cause a reduction of blood volume and shock did not result.

Speaking still of recent theories advanced for the causation of shock, Swingle and his associates¹⁶ stated that the manifestations of surgical shock and deficiency of the adrenal cortical hormone were similar, and they thus proposed the use of adrenal cortical extract in the treatment of shock. Since shock and a deficiency of the adrenal cortical hormone are not related, it is apparent that this theory adds nothing of value to the treatment of shock. Furthermore, the adrenal cortical extract has a slow, prolonged action and, if used in the treatment of shock, its effect will not be manifest until it is too late to meet the emergency.

When so many theories are advanced for the explanation of a condition, it is generally conceded that no one theory can be accepted. This naturally does not preclude the possibility of finding some truth in any one or in all the theories. But the theories cited have provided facts that may be used to advantage.

During the World War the problem of traumatic shock naturally again came to the forefront. Some advances both in its prevention and in its treatment were made, but under the stress of military emergencies conditions for experimental work and careful observation were not always of the best. The large number of cases seen by the military surgeon in combat in a short time could not be duplicated in civil practice even in the most active traumatic surgical service. Despite the tense situation of the World War, valuable contributions were made, and the publications on shock by the Medical Research Committee, the combined observations of both British and American medical officers, are of outstanding interest.

Following the armistice the study of shock from the experimental standpoint was revived. This included not only a critical analysis of existing theories but an attempt to determine the conditions that prevailed in the organism during traumatic shock. It is in this respect that the postwar study of shock has excelled and, despite the controversial points relating to the nature and cause of shock, certain phenomena are now recognized and accepted.

Unquestionably the most striking phenomenon associated with traumatic shock is the decrease in blood volume and the loss of the fluid elements that eventuate, in a concentration of the corpuscular elements. It has been assumed, following the work of Dale, Laidlaw and Richards,¹¹ that the loss of fluid is due to a change in the permeability of the finer vessels of the circulatory tree. In traumatic shock the plasma proteins fall in spite of the fact that the concentration of the hemoglobin increases. One must therefore assume that in this condition the plasma proteins pass from the blood into the intercellular fluids and, as a result of their osmotic effect, draw an additional amount of fluid from the circulation. Acknowledgedly every injury to the tissues is followed by local changes in the circulation. When the injury is severe not only fluid but the cellular elements of the blood gain access to the tissue spaces, and when this transudation is severe enough there occurs a change in the blood volume.¹⁷ Do not these observations adequately explain the reduction in the circulating blood volume and the consequent fall in blood pressure? When the blood pressure or blood volume falls to a critical level, further transudation of fluid from the vessels takes place and the plasma proteins and blood volume decrease simultaneously. Hence in recent years we have come to consider shock as due solely to the loss of fluids into the tissues outside the vascular system.

Freeman noted that dehydration stimulated medullo-adrenal secretion and like injections of epinephrine reduced blood volume. He maintained that arterial constriction rather than dilatation better explained the phenomena of shock. Arterial constriction tends to slow the blood stream and in turn would lead to stasis in the capillaries and the escape of fluid and protein with its attending reduction of the blood volume.

But regardless of the mechanism, the loss of blood volume is a definite reaction to tissue injury and must be reckoned with in treatment. To be sure, fear, anxiety, pain, cold, dehydration and fatigue are contributing factors.

The restoration and maintenance of blood volume may be accepted then as of basic importance in the treatment of shock, and the problem of treating shock is inseparably connected with the maintenance of blood volume. When the degree of shock is severe, no matter what the theories, any or all of the methods of treatment may fail. Paradoxically, it may be said that the time to begin the treatment of shock is before its onset. As preventive measures one must consider the alleviation of pain, of fear and of anxiety. It has been suggested¹ that shock may be relieved by spinal anesthesia, even though the blood pressure is already low. Spinal anesthesia would of course relieve pain, but it is questionable whether it is wise to introduce an additional blood pressure lowering agent in shock, even though certain experiments on animals are reported in which a low blood pressure rose following spinal anesthesia. Mor-

phine is a valuable adjunct to other forms of treatment and prompt attention to the source of painful stimuli is important.

In the treatment and prevention of shock the prevention of psychic trauma too often is overlooked. Intangible as the factor is, I can best illustrate what I mean by recalling the value of what is termed "vocal anesthesia" in conjunction with spinal or local anesthesia. Not only do patients whose mental processes are diverted from the disconcerting ordeal complain less about the operative procedure, but in the case of spinal anesthesia, in which a fall in blood pressure is not unusual, there is stabilization of the pressure. The ability to distract the patient's attention in the treatment of shock is of value in the alleviation of pain. Reassurance to the patient by different means is helpful and taxes the resources of the surgeon.

Lowering the head of the patient and the application of external heat have long been known and accepted as routine procedures.

But if one recognizes the loss of blood volume as the essential etiologic factor, the restoration of blood volume must be acknowledged as the predominant and indispensable agent. In mild shock, intravenous therapy at times causes an immediate relief of symptoms. However, if the patient is losing fluid from the blood stream rapidly and continuously the addition of more fluid is of little service unless the solution can be kept within the circulation. Adequate circulation can be maintained for a short period of time by the introduction of a solution of 10 per cent dextrose and physiologic solution of sodium chloride, but there is need for a solution that diffuses less rapidly. For this reason blood is more efficacious, but if blood is not readily available an acacia solution may be substituted.

During the World War acacia was suggested as a substitute for blood in the treatment of shock by the British physiologist Bayliss.¹⁸ At that time the difficulty of obtaining a pure preparation discouraged the use of acacia and it was almost universally abandoned. Today, however, reliable preparations of acacia in ampules are on the market and may be used without fear of harmful reactions. I have employed this agent when there was need for the rapid restoration and maintenance of fluid volume and have seen no ill effects when it was given in proper concentration. Acacia has again come to the fore in that it is available in stock and convenient containers.

For a time during the World War it was thought that, since there is an associated acidosis in shock, solutions of sodium bicarbonate might be given intravenously to some advantage. Cannon¹⁹ treated several soldiers by this method and was able to cause a transient rise in blood pressure, but this method of treatment was short lived. It has however, during this year been revived by Coonse and his associates.²⁰ It is sufficient to say that the use of a sodium bicarbonate solution is not without danger should it cause an uncompensated alkalosis. In fact I can see no particular advantage in bicarbonate solutions when the same results may be obtained by the much less dangerous physiologic sodium chloride and dextrose solutions.

Recently my attention has been called to the beneficent effect of 10 per cent ethyl alcohol in 10 per cent dextrose given slowly and this I have employed to

advantage. As much as 2 liters may be given intravenously in twenty-four hours. Patients receiving this solution experience a feeling of warmth and well being. Alcohol in the form of whiskey or brandy has long been considered valuable for its stimulating effect and, in addition to its stimulating effect, affords easily available calories.

It must be admitted that during the postwar period definite advances were made in that there was a more accurate understanding of the phenomena of shock, although the mechanism is still not well understood.

How may the treatment of shock be summarized? Primarily, in the removal of all contributing causes. These are not only associated with physical trauma but include psychic, nervous and humoral aberrations. I am not unmindful of the effect of pitressin in maintaining blood pressure and of the stimulating effect of caffeine. But above all these I would emphasize employment of agencies to maintain blood volume. These include saline and dextrose solutions, dextrose and alcohol solutions, solutions of acacia and last, but not least, blood transfusion.

Finally, what is the difference between the treatment of shock in civil life and that in military engagements? It is acknowledged that the treatment of shock should begin at the earliest possible moment, and the treatment of shock in wartime is a matter of organization. How much treatment can be carried out at the first aid stations and how promptly can the injured be transported to field hospitals? These are problems that must be left to the military surgeon, who must keep constantly before him the importance of the avoidance of every unnecessary delay in applying the essential remedies.

3400 Spruce Street

ABSTRACT OF DISCUSSION

DR. CHARLES C LUND, Boston. There is no question that the real treatment for the severe case is replacement of blood. I believe with Blalock and many others that on a quantitative basis the loss of circulating fluid is the essential thing in the picture to which treatment should be directed. There is some unpublished work of Dr. Nowak of the Boston City Hospital, with some elaborate cross circulation experiments, which goes far to confirm this point of view. In every way he seems to show that the loss of fluid into the tissues even when there is no external hemorrhage, produces the largest proportion of the shock in the typical animal experiment. I am in complete agreement with Dr. Frazier that I would hesitate to use sodium bicarbonate at the present moment. Pure acacia solves some of the problems when blood is not immediately available and may be of tremendous importance at first aid stations. I think, though, that the acacia problem is not finished. Acacia stays in the blood a long time. It has been recovered six months or longer after introduction. It is a gummy solution and, according to a pharmacologist, tends to coat and clog the capillaries in the liver. In reasonable amounts, I am sure that it can do nothing but good, but I think that repetitions of doses of acacia say, 500 cc. three or four times in twenty-four hours, and three or four times more in the next twenty-four hours, might be bad, and I would like to see animal work done to find what the upper limit of tolerance of acacia in the way of dosage is. As for alcohol that is a little shocking to the teaching that I have received in physiology. I am interested to hear that its use for shock has been observed by Dr. Frazier and found to be of benefit. The old shock enema with alcohol in the form of whiskey and so on I have always felt was one of the worst things that could be used. Of course, about 10 cc. of pure alcohol per hour would not overload the system at any one time and would be an available source of fuel.

DR. NORMAN E. FREEMAN, Boston. At the Massachusetts General Hospital we have been studying the peripheral distribution of blood to the tissues of the body in cases of shock.

The blood flow in the hand has been determined both in patients presenting the classic picture of shock and in patients whom we believed to be on the road to such a condition. It may briefly be stated that the blood flow in the hand is markedly reduced and may actually be zero in severe cases. This fact is quite in accord with the clinical picture of cold extremities and empty veins, which will not fill with blood even when a venous tourniquet is applied. In other experiments we have tried to analyze the various factors, acting in the clinical cases, which may reduce the peripheral blood flow. The results seem to show that cold, pain, fear and asphyxia depress the peripheral circulation. It is well recognized that these stimuli, together with dehydration and hemorrhage, are all potent factors in producing shock. The consequences of a diminished blood flow are tissue asphyxia and acidosis. Landis has shown that tissue asphyxia leads to an increase in the permeability of the capillaries, allowing plasma to leak out. If the reduced circulation in the hand in cases of shock were also present throughout the body, it can readily be seen how the blood volume would be still further reduced by loss of plasma through asphyxiated capillaries. As Dr Frazier has brought out, the essential dominant feature in shock is a reduced effective blood volume. Any method that raises the blood volume will increase the vital flow of blood to the tissues and thus not only prevent further loss of plasma but actually bring back the blood that is stagnant in the peripheral tissues. The treatment of shock, as Dr Frazier has stated, depends to a large extent on the early restoration of an effective blood volume.

THE TREATMENT OF ACUTE ALCOHOLISM

WITH TEN PER CENT CARBON DIOXIDE AND
NINETY PER CENT OXYGEN
INHALATION

LEON J. ROBINSON, M.D.
AND
SYDNEY SELESNICK, M.D.
BOSTON

For many years the Fifth Medical Service of the Boston City Hospital has been in charge of almost all medical alcoholic patients admitted to this hospital. It is estimated that approximately 700 alcoholic patients are admitted to this service for treatment each year. The opportunity has been present, therefore, to study alcoholism in all its phases.

The acute alcoholic patient¹ generally can be given a good prognosis as to recovery. For this reason, even when medical aid is sought for him, he receives little active therapy. In the paralytic stage of acute alcoholic poisoning, however, emergency treatment may be life saving. Patients in this stage present a picture best described by Sollmann,¹ who states that the symptoms are those of beginning medullary paralysis. Respiration is slow and stertorous, the pulse is scarcely discernible, the skin is cold and cyanotic, the pupils are generally dilated, the reflexes are abolished, the temperature may fall severely. Though death is relatively uncommon, the coma may become deeper and terminate in paralysis of respiration or of the heart, or in pulmonary edema. The patient may die within half an hour after the onset of this paralytic stage. If coma lasts beyond thirteen hours, recovery is rare. Death may also occur later after a prolonged debauch.

From the Fifth Medical Service, Boston City Hospital, John A. Foley, M.D., Physician in Chief, and the Department of Medicine, Boston University School of Medicine.

For the blood chemistry determinations of carbon dioxide, sugar and lactic acid we are indebted to Miss Eunice Smith of the Clinical Laboratory, Boston City Hospital.

¹ Sollmann, Torald. *Manual of Pharmacology*, ed. 3. Philadelphia: W. B. Saunders Company, 1930, pp. 654-698.

as a result of gastric irritation and hemorrhage² or of exhaustion. By analogy with animals it would require about a pint of whisky taken at once to cause coma in man.¹

As it was felt that the best way to combat the condition caused by the ingestion of alcohol would be to remove or lessen the alcohol concentration in the body, rather than merely treat the symptoms of alcoholic depression, a consideration was given to the metabolism of alcohol. Obviously, oxidation of alcohol by the body leads to recovery from acute alcoholism.

METABOLISM AND EXCRETION OF ALCOHOL

Himwich and his co-workers³ state that the ingestion of alcohol is followed by an acidosis resulting from a relative retention of carbon dioxide and an accumulation of lactic acid, causing a diminution of the alkali reserve. They attribute the after-effects, or "hangover," to increased arterial lactic acid. Observing a slight rise in blood sugar levels as alcoholism progressed, they postulate that the blood sugar rises because alcohol spares dextrose, possibly diminishes hepatic oxidation, and the acidosis favors transformation of glycogen to dextrose. They state further that alcohol transforms muscle glycogen to lactic acid.

Sollmann¹ states that less than 2 per cent, and never more than 10 per cent, of alcohol is excreted by the lungs and kidneys. The remainder is completely oxidized in the tissues to carbon dioxide and water (quoting Atwater and Benedict⁴), probably with acetic acid as an intermediate stage.

Mellanby⁵ asserts that alcohol in the body is oxidized at a constant unchangeable rate of approximately 0.185 cc, or 0.148 Gm of alcohol per kilogram per hour, regardless of the amount of alcohol present in the body.

Haggard and Greenberg,^{6b} taking strong exception to Mellanby's view, state that "the rate of oxidation is proportional to the amount of alcohol present," the decrease ranging between 15.9 and 21.1 per cent of the alcohol present.

Concerning urinary excretion of alcohol, in their thorough investigation, Haggard and Greenberg^{6a} find that, although "the concentration of alcohol in the urine bears no relation to the volume of urine secreted, the amount of alcohol eliminated through the kidneys, however, varies directly with the volume secreted," and "the percentage of the total amount of alcohol ingested that is lost through the kidneys depends, therefore, upon the amount of urine passed." They state that "during sixteen hours following ingestion of alcohol from 2.1 per cent to 4.3 per cent of the total amount is eliminated through the kidneys, the variation depending upon the rate of secretion of urine."

Miles⁷ found that from 1.2 to 1.6 per cent of the alcohol appeared in the urine during the first two hours subsequent to ingestion.

Concerning the elimination of alcohol in the expired air, Haggard and Greenberg^{8a} state that "the total amount of alcohol eliminated (in the expired air) in the eight hours following administration was 3.94 per cent of the amount ingested."

Haggard⁸ has shown, using ether, that the rate of elimination of volatile substances through respiration is nearly proportional to the volume of breathing.

Henderson, Haggard and Coburn⁹ and White¹⁰ have shown that the inhalation of from 7 to 10 per cent of carbon dioxide will cause rapid deetherization after ether narcosis.

Haggard and Greenberg^{8a} assert that, by increasing the volume of breathing with inhalation of carbon dioxide, 10 per cent or more of the amount of alcohol ingested can be eliminated in the first hour or two.

Hunter and Mudd¹¹ administered carbon dioxide to three patients in alcoholic coma, each of whom recovered consciousness within half an hour after carbon dioxide was inhaled for thirty minutes or more. They did not determine the blood alcohol concentration. A fourth patient was not unconscious but had some improvement in his thick speech after thirty minutes of carbon dioxide. They also secured a volunteer to drink 28 cc of 95 per cent alcohol on each of two separate days, and blood alcohol determinations were made. On the second day of the test, carbon dioxide was administered for fifty minutes. The blood alcohol curve fell more rapidly than on the first day of the test, when no carbon dioxide had been given.

With carbon dioxide treatment the peak of the alcohol level was reached at about the same time as the curve for the untreated condition. However, it not only started falling a half hour earlier but fell 21.1 mg in the first forty-two minutes of beginning decline as compared to a fall of 57 mg in the control, in the first thirty-four minutes of beginning decline. They did not state whether arterial or venous blood was used.

Van Wulften Palthe¹² found that oxygen inhaled by man and animals largely relieved the symptoms of alcoholic intoxication and that oxygen inhalation prevented death in rabbits which had been given alcohol in doses lethal to control animals.

Barach¹³ asserted that although lethal doses of alcohol caused the same number of deaths among rabbits kept in air as among those kept in an oxygen tent, intoxicated men at rest showed improved sensory function during oxygen inhalation. On withdrawal of the oxygen, the men lapsed into their former state of intoxication. If, however, from 7 to 10 per cent of carbon dioxide in oxygen was given, the improvement was permanent. He concluded that alcohol intoxication is not due to the kind of oxygen want that is susceptible of relief by oxygen inhalation.

PURPOSE OF STUDY

Since carbon dioxide increased the respiratory excretion of alcohol, and since the oxidation of alcohol might be increased through the administration of oxygen, it is conceivable that the inhalation of a combination of

10 per cent carbon dioxide and 90 per cent oxygen mixture might accelerate recovery from acute alcoholic coma, especially of the paralytic state with respiratory depression and cyanosis. If it did no more than keep such a patient from dying of respiratory depression, it would, by keeping him alive, enable him to oxidize the alcohol himself.

It also seemed advisable to determine whether this therapy alone increased the rate of fall in the blood alcohol level. This was accomplished by following the venous blood alcohol curve. Changes in venous blood sugar, carbon dioxide capacity and lactic acid were also followed.

METHODS

The persons selected were alcoholic patients who not only had an odor of alcohol on their breath and a history of drinking alcohol but were comatose, stuporous, drowsy or ataxic.

At the start of the experiment, 30 cc of oxalated blood was obtained from the cubital vein of the arm. The skin was sterilized with 2 per cent aqueous mercurochrome (rather than tincture of iodine, because of its alcoholic content).

An open slot mask connected with a tank containing a mixture of 10 per cent carbon dioxide and 90 per cent oxygen was then placed over the patient's face. The patient was allowed to breathe this mixture for thirty minutes, the expired air passing from the mask out through the open slot. At the end of thirty minutes the inhalation was suspended and 30 cc of blood again withdrawn as before.

In the control cases no carbon dioxide-oxygen therapy was given, here also blood being withdrawn on admission and at the end of thirty minutes.

On each sample of blood carbon dioxide capacity, alcohol, sugar and lactic acid determinations were made. Sodium fluoride was used as a preservative in the portion intended for blood lactic acid and sugar determinations. The blood plasma intended for the carbon dioxide capacity determination was prepared and protected according to the methods suggested by Peters and Van Slyke¹⁴. In the determination of blood alcohol the method used was that described by Turner¹⁵ based on the Naville modification of the Nicloux method. For an account of the method in full, Turner's article is recommended.

RESULTS

Clinically the patients receiving carbon dioxide-oxygen inhalation improved more rapidly than those who did not. However, as our purpose was to obtain chemical substantiation of the clinical observations we will first discuss the laboratory results and then interpolate the clinical results.

Normally, according to Schweisheimer,¹⁶ human blood contains about 0.03 per cent of alcohol, or about 30 mg per hundred cubic centimeters of blood.

Naville¹⁷ asserted that slight intoxication in human beings starts when the blood alcohol content ranges from 0.1 to 0.2 per cent (from 100 to 200 mg per hundred cubic centimeters of blood), is marked at 0.25 per cent (250 mg per hundred cubic centimeters of blood) is grave at 0.3 per cent (300 mg per hundred

cubic centimeters of blood) and is profound (coma or death) at 0.35 to 0.4 per cent (from 350 to 400 mg per hundred cubic centimeters of blood)

It will be noted that in the control group (table 1) at the end of half an hour the blood alcohol level fell little if at all, the greatest fall being 26 mg (1, table 1)

On the other hand, in the group treated with carbon dioxide-oxygen inhalation for half an hour (table 2) in all but two cases the alcohol level, at the end of half an hour, fell more than the greatest fall in the control group. In the two exceptions a rise of 26 mg occurred in one (7, table 2) and in the other a fall of but 8 mg (6, table 2). These apparent exceptions will be discussed later.

The remaining seven cases, then, show a decrease greater than in the control group. In five of these cases (1, 2, 3, 5, 8, table 2), a decrease of 99 mg or more is noted—a fall occurring during a half hour of carbon

accounted for, can be readily understood by a consideration of the following evidence.

Although the concentration of alcohol in the peripheral venous blood, contrary to Miles,⁷ does not reach as high a level as in the peripheral arterial blood, the peripheral arterial and venous blood alcohol concentrations are in close agreement during the period of decline in alcohol concentrations, which decline begins to occur at the end of an hour and a half following alcohol ingestion.^{6a}

From the figures presented by Haggard and Greenberg it seems that although the peripheral venous blood alcohol level never actually represents the height of the arterial blood alcohol level (at its peak the arterial blood alcohol level is 53 per cent higher than the venous) a rise or fall in the venous level reflects a similar though greater rise or fall in the arterial level. They also show that the peak of blood alcohol absorption is

* Rest of blood spilled

dioxide-oxygen therapy, which is sufficient in itself to reduce the blood alcohol from that level causing dangerous coma with respiratory depression and cyanosis to a level which produces the ordinary arousable type of alcoholic intoxication.

In the two other treated cases in which there is a decrease in the blood alcohol level but in which that decrease is less than 99 mg, we still note that one decrease (4, table 2) equaled 53 mg, or twice the decrease in the untreated case showing the greatest spontaneous fall (26 mg, 1, table 1). The other case (9, table 2) shows a decrease of 35 mg, which is still greater than the greatest spontaneous decrease in the control group. However, we will classify the latter case with the other two unsatisfactory or nonspectacular response cases, making three treated cases (6, 7, 9, table 2) which do not show a significantly greater decrease than the greatest spontaneous decrease.

That these do not invalidate the proof of the efficacy of carbon dioxide-oxygen inhalation in causing an accelerated significant decrease in total body alcohol level, and that their apparent paradoxical effect is easily

reached only after one and one-half hours following ingestion.^{6a} Even with intravenous injection of alcohol, in dogs, it required from twenty to twenty-five minutes for equilibration of alcohol concentration between arterial and venous blood and body tissues.^{6a}

We had no way of knowing how long before admission any of our patients had ingested alcohol, because of their intoxicated state. If their last alcoholic drink had been within less than an hour and a half before admission, from Haggard and Greenberg's experiments, it is seen that the blood alcohol level must have been rising. Even though carbon dioxide-oxygen inhalation might have been lessening the total amount of alcohol by increasing pulmonary expiration of alcohol, still some rise in blood alcohol concentration would have occurred, since equilibrium and the peak level would not yet have been reached. The rise might not be great or might even be prevented by a rate of excretion equaling absorption, but a spectacular fall would not be recorded. Thus, we believe, explains the apparent failure to secure an appreciably accelerated decrease in blood alcohol in cases 6, 7 and 9, table 2, which seem not to bear out the results in the remaining cases.

We had considered doing gastric lavage before administering therapy to rule out alimentary post-absorption. It was felt, however, that, by the time these patients were apprehended by the police and brought to the hospital, absorption would be complete. Furthermore, it is now refuted that the alimentary absorption of alcohol is complete at the time the concentration of the alcohol in the blood reaches its maximum.^{6b}

To summarize, it would seem from the foregoing evidence that carbon dioxide-oxygen inhalation definitely accelerates the decrease in venous blood alcohol, that an accelerated decrease in venous blood alcohol with carbon dioxide-oxygen therapy represents an accelerated decrease in total body alcohol, and that, if therapy is instituted before the blood alcohol level reaches its peak, the venous blood alcohol analyses fail to reveal the actual accelerated decrease of blood alcohol that occurs. (One need not be concerned, in actual therapy, as to whether or not this peak has been reached, for obviously administering carbon dioxide-oxygen increases the pulmonary excretion of alcohol and so decreases total body alcohol.)

Carbon dioxide-oxygen inhalations were administered for thirty minutes arbitrarily in order to have a definite control time. In actual clinical work the alcoholic patient in coma can be given carbon dioxide-oxygen inhalations as long as is necessary to reduce the patient from a state of dangerous coma, with cyanosis and respiratory depression, to a state of alcoholic intoxication without respiratory embarrassment.

We wish to emphasize that this is an emergency treatment and is not indicated in the moderate degrees of intoxication so frequently encountered.

CLINICAL RESULTS

In every case of unarousable alcoholic coma, with slow, jerky, shallow respirations and cyanosis, carbon dioxide-oxygen inhalation caused the respirations to become deep and regular almost at once. The patient rapidly turned from a cyanotic cold patient to a pinkish warm one. At the end of a half hour of therapy he had recovered sufficiently so that he could breathe normally when left to himself. He could be aroused by painful stimuli. (Every case treated showed the latter response invariably on the second venipuncture, whereas no response to the first venipuncture was often noted.)

In those patients not in coma but who were stuporous, the reaction to painful stimuli was enhanced and the speech improved following therapy. These patients clinically do not require carbon dioxide-oxygen inhalations at all but in this investigation were used to obtain additional blood alcohol studies.

Patients in alcoholic stupor should be watched for signs of coma, and if coma develops carbon dioxide-oxygen therapy is then indicated, although obviously no harm and much good can be done these patients by carbon dioxide-oxygen inhalations even though they are merely stuporous.

It was not our intention to bring these patients to an immediate state of sobriety but to bring them from coma along the road of recovery to a point at which ordinary moderate intoxication would prevail without respiratory depression. From the latter stage of intoxication in practically all instances patients recover.

To repeat. This is an emergency, not a routine, therapy for acute alcoholism and is indicated only in the comatose alcoholic patient.

OTHER LABORATORY RESULTS

A blood sugar elevation occurs in anesthesia by chloroform, nitrous oxide and ethylene¹⁸ and in morphine narcosis in dogs.¹⁹ Himwich and his co-workers³ report that blood sugar rises in alcoholism also. We cannot confirm their results.

No significant changes in blood sugar levels were found before or after carbon dioxide-oxygen therapy.

Morphine narcosis and also alcoholism were found to cause a rise in blood carbon dioxide content.²⁰ In our series the blood carbon dioxide capacities were low normal or below normal (accepting as normal from 43.3 to 55.9 volumes per cent¹⁴). This is in agreement with the results of Himwich and his co-workers³ to the effect that a carbon dioxide retention occurs in alcoholism.

Carbon dioxide-oxygen therapy had little appreciable effect on the venous carbon dioxide capacity and did not tend to produce a carbon dioxide retention.

The blood lactic acid levels tended to be above normal in all groups (normal blood lactic acid from 10 to 20 mg and possibly 30 mg per hundred cubic centimeters of blood¹⁴). They were not proportional to the concentration of blood alcohol, blood sugar or blood carbon dioxide capacity.

That high lactic acid content causes an acidosis in alcoholism and in anesthesia by ether, chloroform, nitrous oxide and ethylene has been shown.²¹

Long²² asserted that adding carbon dioxide to the inhalation of oxygen caused blood lactic acid to disappear in normal resting human beings.

In this study, carbon dioxide-oxygen inhalation produced no appreciable lowering of the blood lactic acid content, which is in accord with the observations of Ronzoni, Koechig and Eaton,²¹ who reported that the high blood lactic acid concentration in ether anesthesia is not influenced appreciably by the blood carbon dioxide or oxygen tension. It is also in accord with the observations of Anrep and Cannan,²³ who found that the lactic acid concentration in alkalemia and acidemia is not influenced appreciably by the blood carbon dioxide or oxygen tension.

CONCLUSIONS

Acute alcoholic coma with dangerous respiratory depression, paralysis and cyanosis is a medical emergency. Death may be definitely prevented and recovery accelerated by inhalation of a mixture of 10 per cent carbon dioxide and 90 per cent oxygen for a length of time sufficient to reestablish and maintain normal respiration and color even after the inhalation is suspended.

A minimum time of half an hour should be observed. If necessary, the inhalation may be carried out longer.

An accelerated decrease in venous blood alcohol levels is produced by carbon dioxide-oxygen inhalation over a period of thirty or more minutes, indicating an accelerated decrease in total body alcohol.

No significant blood sugar observations were recorded either before or after carbon dioxide-oxygen therapy.

In alcoholic intoxication there was a tendency to lowered blood carbon dioxide capacity. No appreciable change and no carbon dioxide retention was produced by carbon dioxide-oxygen therapy.

The blood lactic acid content was elevated in alcoholism but was unaffected by carbon dioxide-oxygen therapy.

The purpose of the carbon dioxide-oxygen therapy is not to arouse completely a comatose alcoholic patient but to reduce him from a state of dangerous paralytic alcoholism to the less deep stage of anesthesia from which he can safely be expected to recover.

The therapy is recommended as an emergency treatment and is not indicated in the general run of moderately intoxicated patients so frequently encountered.

ROSACEA INTERPRETED AS A BACTERID FROM FOCAL INFECTION

HERMANN FEIT, MD
ELIZABETH ANN LASZLO, MD
AND
FRANK VERO, MD
NEW YORK.

The definition of rosacea is not as easy as one would suppose. The essential characteristics are, first, the location in the midportion of the face, the so-called flush area, second, the chronicity of the disease, and, third, erythemas of different types. In addition to these one may find thickening of the skin, telangiectases, papules, pustules, crusts, scars, seborrhea, and, in cases complicated with acne, comedones. For the patient rosacea is a serious problem chiefly on account of the psychic disturbance caused by the disfigurement. Any physician who has treated many cases knows how unsatisfactory are the therapeutic results and how frequently one sees recurrences in apparently cured cases. The reason for this is probably that most treatment is directed at symptoms rather than at the cause of the disease.

A clinical experience gave impetus to our present study. A woman with a pustular eruption of the face, of several years' duration, consulted one of us. The eruption resembled an iodide acne, but there was no history of iodide ingestion, although it was suspected that iodoform gauze might have been used in the treatment of a recently abscessed tooth. The patient asserted that her teeth were examined every three months by a competent dentist. She made no improvement under local treatment but returned a few months later completely cured after a visit to the Mayo Clinic at Rochester, Minn., and attributed her cure to the draining of a maxillary empyema caused by an infected tooth.

The recovery of this patient was so dramatic that we decided to study the question of focal infection in rosacea further and have since investigated fifty cases. Patients with rosacea applying for treatment at the Vanderbilt Clinic have been studied in cooperation with the School of Dental and Oral Surgery and the Nose and Throat Department for possible focal infections. Examination of the gastro-intestinal and genito-urinary tracts was made in all cases in which the history indi-

cated the possibility of focal infection in these organs. Most patients were tested with toxins or vaccines of bacteria commonly found in infected teeth and sinuses.

The majority of these patients had previously received the usual forms of treatment for rosacea without appreciable improvement, and our efforts were concerned chiefly with the detection and removal of focal infections. The results in this regard are summarized in table 1. The group studied had had rosacea for an average of four years. The proportion of females to males was four to one. The greatest number of cases belonged to the age group of 30 to 40 years. It surprised us that the next largest number belonged to the group between 20 and 30.

FOCAL INFECTIONS

The infections most frequently found were dental (twenty-nine cases). Dr. Daniel E. Ziskin,¹ who made many of the dental examinations, considered as possible foci of infection not only frank periapical abscesses but also advanced periodontoclasia (pyorrhea), pulpless teeth with or without roentgen evidence of periapical infection, and caries with pulp involvement. Five cases of simple caries were included because the recent investigations of Boedecker² on the permeability of the teeth to dyes indicated that toxic material may be absorbed from such lesions. Clinical inspection of the teeth and roentgen examination were supplemented by vitality tests with the galvanic current.

The next largest number of focal infections was found in the paranasal sinuses, of which the maxillary was most frequently involved. The third most frequent type of infection was chronic tonsillitis. In addition, otitis media, cervical adenitis, chronic appendicitis and deep-seated cutaneous infections were considered as possible foci. Eighteen patients suffered from chronic constipation, and Billings³ believed that in such cases the intestine might act as a focus.

Since these cases were tabulated one of us has observed a patient with endometritis whose rosacea has cleared up following curettage.

OTHER ETIOLOGIC FACTORS

Other evidence of pyogenic infection was obtained from the histories. In one case the rosacea began after a puerperal sepsis. Two patients stated that their eruptions began soon after severe attacks of influenza. Seven patients gave a history of tonsillectomy and six of appendectomy in recent years. Two patients had arthritis.

In seven cases, the onset was preceded by some disease of the genital tract necessitating operative intervention such as hysterectomy, ovariectomy, salpingectomy or the removal of fibroid tumors. The last histories could be considered to support the theory of causation either by focal infection or by endocrine disturbance. It was interesting that four of our fifty patients had had thyroidectomies. Twelve patients reported the habitual intake of drugs of which phenolphthalein was the most frequent. Phenobarbital, acetylsalicylic acid and bromides were also reported.

Demodex folliculorum was found in a large number of our cases although not in all. The technic used was that advised by Ayres and Anderson.⁴ The fact that

From the Department of Dermatology, Vanderbilt Clinic, Columbia University College of Physicians and Surgeons.

this parasite is found in many other dermatoses made us doubtful as to its pathogenic significance. It must be admitted that in some of our elderly patients whose foci of infections could not be removed the rosacea improved greatly under the use of an ointment⁵. We did not, however, feel certain that this improvement was due to antiparasitic action.

SENSITIZATION TESTS

In twenty-seven cases intradermal skin tests were made with staphylococcus toxin prepared by the method of Parker⁶ and streptococcus toxin prepared by the method of Wadsworth⁷ (table 2). These toxins were used in dilutions (1:10 to 1:50 for the staphylococcus toxin and 1:400 for the streptococcus toxin) which had been found to give few positive reactions in the Allergy Clinic. Of this group, seventeen gave an immediate and thirteen a delayed reaction to the staphylococcus toxin, five an immediate and seven a delayed reaction to streptococcus toxin. Thirteen cases were also tested with a colon bacillus vaccine prepared for us by Dr R. Lyons⁸ from a hemolytic strain of colon bacillus. It consisted of 1:1,000 suspension of sedimented bacteria killed by heating to 60°C for one-half hour. Previous tests with this vaccine on a number of patients by one of us (E. A. L.) had shown very few positive reactions. Of thirteen cases two showed immediate and nine delayed reactions. A number of patients also reported a flare up of their eruption (focal reaction) after the intradermal tests.

TABLE 1—Focal Infections

| | Cases | |
|---|-------|----------|
| Number of cases: | | |
| Male | 60 | |

| Improved | 12 | 24 |
| Unimproved | 1 | 2 |
| Unknown (patients could not be followed up) | 10 | |

Stool examination of several patients showing a positive reaction to *Bacillus coli* showed the presence of hemolytic strains in the intestine.

RESULTS FROM THE REMOVAL OF FOCAL INFECTIONS

We have considered as cured cases in which the skin returned to normal except for the presence of telangiectases and scars and which remained clear during our period of observation, which varied from one to three years as greatly improved cases which showed no papules or pustules but some erythema and as improved cases in which papules and pustules of diminished

number and severity continued to develop. It is probable that the results would have been better were it not for the refusal of some patients to undergo the various operations indicated, such as dental extraction and tonsillectomy. In some elderly patients the advisability of such an operation seemed questionable. It should also be borne in mind that, as Billings has emphasized, foci of infection are often multiple, that a patient may develop one primary and then a number of secondary foci, and that only the successful removal

TABLE 2—Sensitization Tests

| | Number of Cases | Immediate Reaction | Delayed Reaction | | |
|------------------------|-----------------|--------------------|------------------|----------|----------|

of all foci can insure the patient against reaction from the bacteria concerned. It should be stated that it was necessary to give some patients mild local treatments or ultraviolet radiation in order to keep them under observation. The majority had, however, had similar treatments before without appreciable improvement, and we do not think that the use of these accessory measures invalidates our conclusions as to the effectiveness of the removal of the foci of infection.

COMMENT

The etiology of rosacea is probably complex. One observes three types of erythema—in early cases a bright redness of the cheeks and nose which makes the skin hot and is undoubtedly due to active congestion with increased velocity of circulation. This hot redness comes on in attacks of varied duration. Later one sees a dusky bluish redness with a cold skin. This is probably due to passive congestion and a diminished velocity of the blood flow. This cold redness is more chronic and often accompanied by thickening of the skin and visible dilatation of superficial venules. It is the condition called by the French, "couperose," and seems to be the essential symptom of rosacea. The disease may stop here. Later one may see a third type of erythema consisting of transitory red blotches, which are hot, indicating active congestion and which frequently occur alone or associated with papules and pustules. The capillary bed of the cheeks reacts more violently than that of other areas of skin to various physiologic stimuli. These areas also seem especially susceptible to injuries which lead to paralysis or weakening of the walls of the small vessels.

It cannot be accidental that this disease as well as lupus erythematosus, lupus vulgaris, syphilis, leprosy and certain drug eruptions so frequently localizes in the so-called flush areas of the face, that is, the central portions of the cheeks and the lower portion of the nose. The coldness of the skin in chronic rosacea indicates that the capillary circulation is sluggish. The visible superficial venules undoubtedly represent places of slowed circulation, and Thibierge⁹ and others have described dilation and even sacculatation of the venules of the deep corium. It seems possible that this slowed circulation offers a mechanical explanation of the susceptibility of such areas to injury by bacteria or toxins.

gaining access to the blood stream. This situation seems similar to the condition observed in other areas which leads erythema induratum to localize on the lower legs and chilblain lupus to localize on the nose and fingers.

The hypotheses suggested as the cause of rosacea are too numerous for us to attempt to discuss here. Emphasis has been laid by most writers on gastrointestinal disturbances, endocrine disturbances and so forth. Wile,¹⁰ Stokes,¹¹ Andrews¹² and others mention focal infection as a causative factor, but the importance of such infections has not been stressed. Linser¹³ considers rosacea an allergic reaction of elderly persons toward the commonly found pyogenic bacteria; he found a more pronounced reaction in the areas of rosacea than on the normal skin areas of the arm to staphylococcus vaccines (freshly prepared, concentrated, centrifuged and killed cultures) and believed that he was able to desensitize his cases. We believe that the fact that so many of our cases cleared up or improved after the removal of the foci of infection indicates that rosacea, or at least the pustular lesions of rosacea, could be interpreted as bacterids. We use this word as analogous to other "ids" to denote lesions due to access of bacteria or to their toxins to sensitized areas of skin which are caused not by the invasive growth of the bacteria but by an allergic reaction to them.

The detection of such bacteria in the blood stream would be difficult, because they probably invade infrequently and in small numbers. Micro-organisms do not long survive in the "ids" that they produce. We cannot prove that the bacteria fail to proliferate in the pustular lesions of rosacea, because such lesions are apt to be secondarily infected with staphylococci or streptococci from the skin surface. The evidence of cutaneous allergy to these bacteria obtained by our skin tests supports this point of view. We were particularly interested in the reactions to the colon bacillus, which suggest that the intestine may act as a focus of infection in some cases. The lesions would seem analogous to the rosacea-like tuberculid of Levandowsky, which is presumably caused by invasion of sensitized areas by the tubercle bacillus. It also seems analogous to the pustular bacterids of the hands and feet described by Andrews.¹⁴

The third type of erythema, the blotchy, active hyperemia, would seem to be caused by bacterial sensitization. Whether the other erythemas are due to focal infection seems more doubtful. There is much to suggest that endocrine or other factors affecting the neurovascular mechanism in this area may play a role. It was striking, however, that in a number of our patients not only the pustulation but the diffuse chronic erythema disappeared after the removal of the foci of infection. The deep acne of the chin, according to Brocq,¹⁵ who devotes a whole chapter to this form of acne, is mostly found in women at the age of 25 to 45 and belongs, in our opinion, to rosacea. These women have

endometritis, disturbances of the ovaries, tubes, menstrual disorders, and congestive flushes from the uterus and are very recalcitrant to treatment. The skin is bluish and cold, and very few if any comedones are present. The patients are not in the acne age nor have they acne lesions in the usual locations. Several such cases were observed only recently by one of us which cleared up after removal of the foci of infection.

SUMMARY

1 Fifty cases of rosacea were studied from the standpoint of focal infections.

2 In 86 per cent various focal infections were found.

3 Removal of these foci resulted in fourteen cures, thirteen greatly improved, twelve improved, and one unimproved, ten were not observed for a sufficient length of time. It goes without saying that for many reasons not all foci could be removed.

4 The close relationship between foci of infection and bacterids is apparent.

952 Fifth Avenue—162 East Eightieth Street—111 East Seventy-Fifth Street.

ABSTRACT OF DISCUSSION

DR SAMUEL AYRES JR, Los Angeles. For the past five or six years I have been studying the problem of rosacea and I have been conscious of the importance of focal infection in the etiology of certain skin disorders. I have not, however, associated these two ideas. Most of the older textbooks stress the importance of gastro-intestinal disturbances, hypochlorhydria, alcohol indulgence, and so on. More recently three other etiologic factors have been emphasized. Dr Anderson and I called attention to the probable causal relationship of *Demodex folliculorum*. Stokes and Beerman considered psychic factors of great importance and pointed out that they frequently led to secondary functional disturbances, which in turn produced rosacea. And now our attention is called to the possibility that the lesions of rosacea may represent bacterids. All three theories are probably correct as applied to certain types of cases. A fourth type of erythema in our experience has been the commonest and is the type usually associated with *Demodex* infestation. This type of erythema is usually the earliest manifestation and persists relatively unchanged throughout the course of the disease except for occasional exacerbations or sometimes a gradual increase in intensity. It may be diffuse or somewhat blotchy and is most pronounced on the central portion of the face, including the medial aspects of the cheeks, lower half of the nose and middle of the forehead. One or more of these areas may be involved. The skin is usually dry and nearly always characterized by minute dry follicular plugs or scales. This appearance is so characteristic that we have given it the name pityriasis folliculorum (*Demodex*) when the pustular element is lacking. In addition to the redness and insignificant scaling there usually are a few scattered extremely tiny superficial vesicopustules. Some cases show severe papulopustular elements. One patient, whose condition had resisted all manner of treatment, was completely cured by an antiparasitic ointment. However, the most characteristic features of this fourth type of erythema are the dryness, the follicular scaling and the minute vesicopustules. In many cases the entire picture is inconspicuous. The patient is usually a woman who complains that her face is so dry that she can't use soap. In our experience *Demodex* can be found readily in large numbers in the majority of cases of rosacea by simply picking off a few follicular scales or taking a droplet of pus from several of the superficial vesicopustules and examining them under the low power of the microscope after adding a drop of 40 per cent solution of potassium hydroxide. In contrast, we have found *Demodex* only rarely in superficial or deep pustules in many cases of acne vulgaris or sycosis vulgaris, which we consider an adequate control. Furthermore, under the local application of a strong antiparasitic ointment such as the one mentioned by the authors,³

there is rapid clinical improvement, often as much as from 80 to 90 per cent within one or two weeks, accompanied by a progressive decrease in the number of *Demodex* organisms that can be found

DR. MYER SOLIS-COHEN, Philadelphia In acne rosacea and acne vulgaris I take cultures of the nares, nasopharynx and tonsils or tonsillar fossae, and sometimes the urine and feces, in addition to the pustule. Many physicians fail to realize that the removal of infected tissue does not necessarily remove the focus of infection, because infecting bacteria may remain behind on adjacent tissues. Instead of the bacterial origin having failed as the authors say, may it not be that every possible focus has not been examined and that a focus has been regarded as removed when the infecting bacteria have been still present? As bearing on the question as to whether the cause is a germ or a bacterid, I find the same organism in the pustule and in the nares, throat or infected tooth. I regard the skin lesions as secondary and believe that the primary focus is commonly in the upper respiratory tract and the mouth. Gastro-intestinal and urinary infections I look on also as secondary. In many instances I feel that a tooth infection is secondary, a devitalized tooth being a place of lessened resistance, which becomes infected secondarily by organisms from the nose and throat. Experiments I made several years ago showed a lack of correspondence between bacteria that were infecting the patient and those producing a reaction when injected intracutaneously. An acne or other secondary lesion is seldom cured merely by the removal of infected tissue or the drainage of an infected cavity at the primary focus. As a rule it is necessary in addition to raise the patient's resistance to the infecting organism by means of a potent vaccine that contains this infecting germ and its soluble exotoxin. In chronic and focal infections, however, the organism that appears or predominates in a culture is not always of etiologic significance. I employ the pathogen-selective culture in which the inoculum is planted simultaneously in a rich culture medium and in the patient's whole, coagulable blood. Organisms killed by the patient's blood are regarded as having no causal relationship to the infection, while those that survive in it are believed to be important etiologically. Remarkable and rapid cures of long standing cases have followed this method of treatment.

DR. E. S. LAIN, Oklahoma City Treatment is not the central theme for this discussion, however, it is closely related to it. Several years ago when it seemed to have become generally accepted that focal infection was a cause of lupus erythematosus, and after having previously noted for quite a period of time the close relationship between lupus erythematosus rosacea, remembering also that many cases of rosacea in certain patients seemed sometimes to resemble tuberculid, I thought of trying gold in the treatment of rosacea. I have found that in a series of some fifteen or twenty cases the treatment of certain types of rosacea with intravenous gold is almost if not entirely as satisfactory as in the case of lupus erythematosus though without clearing the focal infection. Of course, it is also subject to the same relapses. In our clinic, gold in rosacea has now become almost a routine treatment instead of roentgen therapy, though our number of cases is small compared to that of others.

DR. JOHN H. STOKES, Philadelphia It is easy to say the cause. I wonder whether something might not be gained by dermatologists forming a habit of speaking of the predisposing and the exciting causes. Focal infection is undoubtedly an element. So equally without doubt on the California coast is *Demodex* and so equally perhaps is the deficiency of hydrochloric acid in the peculiar intestinal flora which these patients develop. If one will concede the process to be a complex one, peace can be brought into these warring camps, and it is much easier to understand why one fails in an acne with this, why another fails in a rosacea with that and why he also succeeds with something else. If he speaks of the rosacea background which is the vascular element in the situation, and analyzes it into four or five constituents he can then readily concede that a focal infection is perhaps the thing that pulls the trigger on the predisposing causes in a particular case. In the end this kind of multiple factorial analysis of a great many complex causal pictures in dermatology will bring a very much better

understanding of the situation. It is difficult and extremely unwise to speak of sole causes in many dermatoses.

DR. HERMANN FEIT, New York As Dr. Ayres brought out in his group of patients who live in California and belong to the better class of people, he finds a great many cases of *Demodex folliculorum*. It is interesting that a parasite of this kind is able to produce one of the erythemas. Dr. Solis-Cohen partly agrees with our observations as to the removal of focal infection to remove the symptom complex. Dr. Lain stated that he treats his cases of lupus erythematosus in the same way that he treats the cases of rosacea. As I tried to show in our diagram, it cannot be accidental that this butterfly pattern of the face is found in so many diseases, but I cannot agree with him that one should use the gold preparation, which has many dangers. It is not justified, in my opinion. I have seen quite a few accidents from gold. It is not indicated unless one is dealing with a tuberculous lesion. I don't know whom Dr. Stokes referred to when he said the cause of rosacea. If I said that focal infection is the cause of rosacea, I tried to explain that these bacterids come on only after the two first erythemas have developed. I think that I said purposely that in most cases the disease stopped at the second erythema, the congestive erythema, of which I showed the picture. Naturally, up to this point focal infection has absolutely nothing to do with the disease, and all the other factors that are so well known are the causes of this peculiar mechanism, but after this is established and the patient has a focal infection we believe that when it comes into the circulation it causes these papular and pustular eruptions.

TRAUMATIC SEGMENTARY ARTERIAL SPASM

ALBERT H. MONTGOMERY, M.D.

AND

JAY IRELAND, M.D.
CHICAGO

Every surgeon knows the serious consequences that may follow traumatic injuries that interfere with the necessary blood supply to any part of the body, especially the extremities. When the vascular obstruction is the result of something that was done in the course of a surgical operation or manipulation, the condition assumes a tragic aspect not only for the patient but also for the surgeon. Particularly in work on the extremities the surgeon is kept constantly on the alert in regard to the blood supply by visions of possible gangrene, amputation, ischemic palsy and malpractice suits. However, despite our knowledge and vigilance, accidents to a vital blood supply may occur and it is possibly safe to say that most surgeons of experience have encountered an alarming situation of this kind. Vascular trouble may arise from a number of very common agents, such as tourniquets, constricting splints, too tight suturing, the injection of anesthetic or sclerosing substances, or subfascial hematomas.

In our work at the Children's Memorial Hospital we have been confronted with two cases of arterial obstruction following operative procedures on the arm. The threatening clinical picture presented in these two cases and the fact that they did not seem to result from any recognized causative factor has prompted us to describe our observations in detail.

CASE 1—A boy aged 9 years, of Polish descent, entered the Children's Memorial Hospital Sept. 30, 1930, with a history of having fallen down stairs about four weeks previously, injuring his right elbow. Following the accident the child complained

From the Surgical Service of the Children's Memorial Hospital and the Department of Surgery of Rush Medical College of the University of Chicago.

of pain in the arm and the mother noticed that the elbow was swollen and discolored. No treatment had been administered except that his mother had applied alcohol and hot water bottles to his elbow. There was no history of any previous illness to be obtained and his family history was unimportant.

The physical examination was negative except for the right arm. The right elbow, which was larger than normal, was held in an extended position and could not be flexed. The condyles were displaced medially and posteriorly.

Roentgenograms showed a comminuted fracture through the condyles of the humerus, with posterior and median displacement of the fragments and callus formation. There was also a median dislocation of the radius and ulna.

An open operation under ether anesthesia was performed October 4, thirty-four days after the injury and the bone fragments were aligned and the dislocation of the radius and ulna was reduced. There was some difficulty in manipulating the bones into line, necessitating a definite amount of trauma to the soft tissues during the operation. The elbow was dressed in flexion at 90 degrees with a posterior molded splint. One hour after operation it was noticed that the forearm, hand and fingers of the injured arm were dead white and that no pulse was palpable in the radial and ulnar arteries. The dressings were immediately opened and the arm extended but no improvement in the circulation followed. Then in the fear that the wound had been sutured too tightly or that a ligature or suture had been inadvertently placed about the brachial artery the child was again anesthetized and the wound reopened. When the arteries were exposed it was evident that there was no visible or palpable pulsation in the brachial, radial or ulnar arteries and all three vessels appeared to be smaller than normal with no macroscopic evidence of injury. There was no indication of a thrombus formation and no ligature or suture was around any of the arteries. The wound was left open and warm moist dressings were applied with the arm elevated.

One hour later the ulnar pulse was palpable at the wrist and the color of the hand had returned to normal. The radial pulse did not return to normal until two days later. The wound was resutured five days after the second operation. No vascular disturbance followed and the healing was uneventful. When last seen, four years after the injury, there was no sign of circulatory trouble in the arm.

CASE 2—A Polish boy, aged 5 years, entered the Children's Memorial Hospital April 28, 1934, complaining of an injury to his left elbow, sustained in a fall one hour before coming to the clinic. He had never had any serious injury before and the personal and family history was essentially unimportant.

The physical examination was negative except for the left arm, which showed a fusiform discolored swelling of the left elbow with a lateral angulation of the arm below the site of injury and marked tenderness over both condyles of the humerus. The condition of the forearm and hand was very striking. The skin everywhere distal to the elbow was dead white and distinctly colder than that of the opposite hand and forearm. No pulsation could be palpated in the radial or ulnar arteries of the injured arm.

Roentgenograms of the left elbow showed a supracondylar comminuted fracture of the humerus with marked lateral displacement of the lower fragments, and a posterior dislocation of the radius and ulna.

Four and one-half hours after the injury an attempt was made under nitrous oxide anesthesia to reduce the fracture dislocation. The manipulation apparently had no effect on the circulation of the forearm, for its appearance remained unchanged with no sign of any pulsation in the radial and ulnar vessels. The condition seemed to demand immediate relief, so the anesthetic was continued and the fractured area was exposed by an open operation. A large hematoma was removed from the antecubital region, but the distal circulation remained unchanged. Pulsations were seen and felt in the brachial artery down to within an inch of its bifurcation but not distal to this region, and no pulsations were present in the exposed radial and ulnar arteries. The pulsation ceased at a definite localized place as though the blood were striking against a solid structure. All three arteries appeared smaller than normal. There was no visible contusion or any laceration of the arteries, and no thrombus could be felt.

The arteries were not incised, but the wound was left wide open and warm moist dressings were applied with the arm elevated. On the following day the radial and ulnar pulses were still absent, but the hand was warm, the nails were not completely blanched, and after pressure on the skin there was some visible return circulation.

Three days after operation a weak but inconstant radial pulse was palpable for the first time since the injury. It improved very gradually, so that thirty days following the accident it was similar to and remained like that of the normal right arm.

May 9, eleven days after the first operation, the wound was sutured and a posterior molded cast was applied. The wound healed kindly and on June 20, fifty-three days after the injury, the fracture and dislocation were reduced by open operation with no circulatory disturbance.

We have presented here two cases of occlusion of the brachial artery, one immediately following a simple supracondylar fracture of the humerus and the other after an open operation to reduce a similar fracture. The absence of any pulsation was demonstrated by operative exposure of the vessels, but no evident cause for the condition could be found.

Our rather trying experience with these two cases which presented a condition with which we were unfamiliar led us to look up the literature on this subject. All the references were by continental European surgeons and by Farani,¹ a Brazilian. The earliest report we found was by Kroh² in 1915. He described two cases of traumatic arrest of the blood flow in the large arteries of the extremities following war wounds. On operative exposure of the vessels they appeared normal except that they were contracted in size. After massage in one case the circulation became reestablished. In the second case the femoral artery was seen to be contracted to the size of a knitting needle. To the author's surprise he noticed while the artery was exposed that it dilated to its normal size. In 1917 Kroh reported a third case involving the brachial artery. During operation the vessel was seen to be collapsed, but it dilated to its normal caliber after massage. In 1920 von Kuttner and Baruch³ collected fifteen case reports and added eight cases of their own. We have found reports of seventeen cases published since that time. The addition of the two cases that we have described brings the total of reported cases to forty-four up to date. In many instances the reports were fragmentary and incomplete, so that deductions are rather difficult to make.

This vascular disturbance has been designated by various authors as "arterial stupor," "arterial contusion" and "traumatic segmentary inhibition of arteries." We have chosen to use the term traumatic arterial segmentary spasm, as it seems to be the most descriptive of this condition in which no pathologic changes are demonstrable in the affected vessels. Lexer⁴ has stated that of all the vessel coats the intima is the most susceptible to trauma. However, it does not seem probable that the intima of the arteries in our cases could have been loosened enough to obliterate the lumen and yet allow the pulse to reappear after such a short period of time. Moreover, in the cases in which the affected segment of the artery was excised for treatment, the intima as well as the other vessel coats was found to be unchanged.

The vascular obstruction seems to be confined for the most part to the large arteries of the extremities. In this group of cases the femoral artery was affected in sixteen instances, the brachial artery in thirteen, the radial, popliteal and posterior tibial arteries three times each, the axillary twice, and the external iliac and the carotid once each. The causative factor in every case was some definite trauma. In twenty-six instances, many of them war casualties, the condition was ascribed to gunshot or high explosive injuries. Fractures involving the femur, radius or humerus were reported in ten cases. Among the other causes mentioned were a kick by a horse, a fall, vehicle injuries, airplane propeller contusion and operative wound trauma. It is noticeable that the gunshot injuries and fractures are blamed for thirty-six of the forty-four cases in this series.

The manner in which these traumatic agents produced such striking vascular changes has been a matter for discussion. Thrombosis must be considered, but in no case was a thrombus palpable and in those cases in which the artery was opened no thrombus was found. It does not seem probable that a thrombus would be removed or become canalized so rapidly that the circulation would return as soon as it did in these cases. Blood clots pressing on the artery were found in some cases, but their removal did not relieve the obstruction in any instance, and in the fracture cases there was no evidence of pressure of bone fragments on the arteries. From the absence of any pathologic change involving the artery and the complete return of circulatory function after a brief period, it would seem that the condition is one of arterial spasm probably on a basis of nerve disturbance, very likely a sympathetic nerve imbalance causing a spasmodic constriction of the artery. This theory is favored by Kroh, Reichle⁵ and Finally.⁶

That such a condition as vascular spasm exists is quite generally admitted. Makins⁷ noticed that in a certain proportion of wounds in close proximity to large vessels a diminution of the normal caliber of the arteries was present shortly after the injury. Leriche⁸ stated that oscillometric tests proved every traumatism in man to be a traumatism to vasomotoricity, furthermore, that always after a shock or a blow, though there is no wound or fracture, the peripheral nerve endings are excited and by reflex action, will immediately disturb the equilibrium of the vasomotor system for a shorter or longer period of time. Leriche and Heitz⁹ regarded an obliterated main vessel as a "nerve" the fibrous cord of which represents the segment of the vasomotor chain, since it contains the remnants of the perivascular sympathetic. Moreover he thinks that the "nerve" is abnormal and has functions which are distorted.

Makins,⁷ in discussing thrombosis, stated that the vessel may be narrowed both above and below the thrombosed spot and added that this was a condition usually seen when the normal arterial circulation is arrested either by a thrombus or by a large wound involving the lumen. Although he did not state that this is due to a nervous influence, it does indicate that some mechanism can affect a vessel causing it to be constricted enough to be visible to the naked eye.

Coller and Maddock¹⁰ classify Raynaud's disease as a type of arterial spasm and state that pure spasm may be associated with other conditions such as anterior poliomyelitis. Morton and Scott¹¹ reported four cases of angiospasm following trauma in which painful spastic attacks were produced by exposure to cold, as in a case of Raynaud's disease, and Kerr noticed that during an attack of Raynaud's disease the radial pulse could not be felt in his patients. Lewis and Kerr,¹² in discussing this disease, stated that the vasodilatation is held in check or prevented by a simultaneous tendency to vasoconstriction. In the cases comprised in this report only the large arteries were involved, whereas according to Royle¹³ in Raynaud's disease the small arteries and arterioles are the vessels that are affected.

Besides the evidence that sympathetic nerve involvement may cause arterial contraction there is also some evidence that somatic nerve involvement causes vascular changes. Bardenheuer¹⁴ stated, in relation to fracture, that injury to the nerves often results in circulatory disturbance. Stapford¹⁵ reported histologic changes found in the arteries of a limb in which the popliteal nerves were injured without damaging the popliteal vessels. Microscopic examination showed an endarteritis in the walls of the dorsalis pedis artery.

Also, some evidence has been produced to show that not all vascular changes are under nervous control. Kerr stated that local areas of blanching may appear in a skin that has been deprived of all nerve supply. This suggests a chemical factor that may control the size of the vessel, as hypothesized by von Kuttner and Baruch. Recently Snithwick, Freeman and White¹⁶ showed that epinephrine caused marked vasospasm in man following complete sympathetic denervation of the extremities, and Odermatt¹⁷ injected epinephrine perivascularly and was able to produce arterial spasm.

Von Kuttner and Baruch, Winterstein¹⁸ and Laqua¹⁹ favor the myogenic or arterial musculature contractio basis as the causative factor.

Veau, Viannay, Lacoste and Ferrier²⁰ recognized three states of traumatic segmentary arterial spasm

1 The lowest state This is a vasoconstriction detectable only by the sphygmomanometer There is only a partial arrest of arterial circulation

2 State of confirmed stupor In this type there is complete arrest of circulation

3 Grave state This is characterized by a complete permanent arterial circulatory arrest with gangrene of the extremity from the very beginning

Probably similar states may occur elsewhere in the body This vascular disturbance may be somewhat analogous to the condition of local nerve shock following gunshot wounds in which there is a temporary loss of sensation and power in the injured limb A similar explanation may be given to the absence of hemorrhage in completely divided arteries lying exposed in an open wound Also, such a condition may be present in the occurrence of cerebral symptoms that immediately follow injury or ligation of the carotid arteries

The diagnosis of a case of arterial spasm following injury is very difficult without operative exposure of the artery, as was done in our cases However, such diagnoses have been made by Farani without previous experience and also by others after experience with a few cases One wonders whether some of the measures used in other vascular diseases might be of diagnostic value in traumatic segmentary arterial spasm Brown²¹ employed intravenous injection of a foreign protein typhoid vaccine, as a test for vascular spasm He showed that in spastic vascular disease of the arteries the injection of foreign protein causes the extremities to become decidedly warmer but that in obliterative disease the increase in temperature is none or very slight For a similar purpose Morton and Scott suggested the use of local, spinal and general anesthesia and they interpreted their results similarly to Brown's However, general anesthesia was employed in both our cases with no subsequent rise in temperature The Pascon oscillometer would be of diagnostic aid in the mild cases in which occlusion is not complete

Lexer stated that a positive diagnosis of complete rupture or closure by thrombus formation of the principal artery can be made if after injury the extremity becomes cool, pale or cyanotic and the pulse can no longer be felt Our cases showed these symptoms, yet no thrombus was present Thus arterial spasm can exhibit a clinical picture that would tend somewhat to disprove Lexer's statement

The time of disappearance of the spasm is fairly uniform In most of the cases the spasm had disappeared in twenty-four hours In a case of Soubeyran and Michon²² the spasm was present to some extent for more than a year In our cases the radial pulse returned in one hour in one instance and not until the third day in the other, although signs of improved circulation were evident after twenty-four hours

The outlook in cases of arterial spasm is good so far as life is concerned, as there was only one death in this series that was attributable to the vascular condition

In that case the artery was exposed and massaged When this failed, a segment of the artery was excised and death ensued One other death occurred in this series but it was undoubtedly due to shock, as the pulse in the femoral artery returned to normal after hot serum irrigations The foot became warm and the posterior tibial pulse was palpable

Amputation of the limb was performed on six of the forty-four patients because of gangrene Four patients had sustained gunshot wounds that caused infection and arterial spasm A similar condition occurred in another case following a lacerated wound In the final case the gangrene was probably due to improper treatment. The arterial spasm complicated a simple fracture of the femur The femoral artery was exposed in three places Hemorrhage and gangrene followed, necessitating amputation

Concerning the treatment, there seems to be no doubt that the conservative measures should be tried first When the diagnosis of traumatic segmentary arterial spasm is most probable, it is suggested that if a recent fracture or dislocation is present it should be reduced or that if some other mechanical cause is found for the absent pulse it should be removed If this fails to bring about a return of the circulation, an open operation should be undertaken immediately and the artery exposed at the site of the trauma However, Farani and Reichle do not subscribe to this view Farani did not operate on any of his three patients and all recovered Reichle suggested that one might wait eighteen hours before operation is undertaken to see whether the circulation will return Most surgeons, however, will probably not have the diagnostic ability or the fortitude to employ this passive treatment but will feel that their patient and their own peace of mind will be served better by an open exposure of the artery If this shows an arterial spasm, the simple treatment that was used in a number of the cases in this series, including our own, would seem to be sufficient The wound is left open and continuous warm moist dressings are applied, with the arm kept at rest in elevation

Various surgeons have employed other methods Kroh massaged the artery in the open wound and the circulation returned to normal immediately Ducastaing²³ successfully irrigated the exposed artery with warm serum, but Soubeyran failed with this method. Von Kuttner and Baruch suggested the use of atropine but evidently did not employ it

Incision into the artery to search for the thrombus was considered in our second case but fortunately it was not done In opening into the artery one must always remember that suture may not be successful and that a thrombosis or vessel hemorrhage may occur and make vessel ligation mandatory After four cases of simple ligation of the brachial artery complicating fracture of the humerus, Makins had a resulting gangrene in three instances

For the more grave cases in which the arterial spasm does not yield to the simple methods, periarterial sympathectomy, ganglionectomy and concomitant vein ligation have been suggested Ligation of the artery or excision of the affected segment of the artery would seem to be contraindicated in the treatment of this acute condition but might be tried

Possibly one of the most promising methods of treating peripheral arterial occlusion is that recently

employed by Reid²⁴ and his associates, who use intermittent increased and decreased air pressure by means of an air tight chamber applied to the extremity

Amputation should be performed only as a last resort when a definite gangrene is present. We mention this particularly because among the six cases in this series in which amputation was done there is one reported by von Kuttner and Baruch in which the limb was removed under the impression that the artery was thrombosed or severed but the vessel was found to be normal

We are aware that this subject of traumatic segmentary arterial spasm may be more familiar than the literature would indicate. The knowledge that we have gained in our two experiences will be a comforting reassurance to us in our future work

SUMMARY OF PREVIOUSLY REPORTED CASES

A brief summary of the previously reported cases is as follows

CASE 1 (reported by Kroh)—Sex and age unstated. Patient received a revolver wound of the right groin. The femoral artery was exposed at an open operation and a segment of the artery, 5 cm in length, was seen to be contracted to the size of a knitting needle. The exposed artery was watched for five minutes and then it dilated to its normal size. The saphenous vein had been shot across. Recovered.

CASE 2 (reported by Kroh)—Sex and age unstated. Patient was wounded in the femoral region by an infantry shot. The artery was not operated on but the leg was massaged and the femoral pulse was normal in twenty-four hours. Recovered.

CASE 3 (reported by Kroh)—Sex and age unstated. Injury was a gunshot wound in the humerus region. At an open operation the contracted artery was massaged and it dilated in the wound to normal size. Recovered.

CASE 4 (reported by Viannay)—Male, age unstated. Injured by an airplane propeller in the region of the brachial artery. At open operation 5 cm of the clavicle was resected and the sheath of the artery only was opened. Recovered.

CASE 5 (reported by Viannay²⁵)—Male, age unstated. Grenade injury. Axillary artery involved in spasm as seen in open operation. Artery was not disturbed. Recovered.

CASE 6 (reported by Viannay)—Sex and age unstated. Grenade wound in the axillary region. Open operation was performed on the arm but the axillary artery was not disturbed. Recovered.

CASE 7 (reported by Viannay)—Sex and age unstated. Grenade wound. Radial artery involved in spasticity. Open operation and segment of the artery excised. Recovered.

CASE 8 (reported by Viannay)—Male, age unstated. A bullet wound of the left femoral region. Treated by open operation and a segment of the artery was resected, after which the artery bled. Recovered.

CASE 9 (reported by Lacoste and Ferrier)—Boy, aged 14 years. Sustained a subtrochanteric fracture of the femur. Cause unstated. Leg was placed in an extension apparatus. Arteriotomy was performed in three places. Gangrene of the leg and amputation followed. Recovered.

CASE 10 (reported by Fiolle²⁶)—Man aged 22. Received a bullet wound in the femoral region. At open operation massage of the femoral artery failed to cause return of circulation. Segment of artery was excised. Died.

CASE 11 (reported by Soubeyran and Michon)—Man, aged 22. Infantry shot of the femoral region. Femoral artery involved. At operation only the artery was exposed. For a year following the patient suffered from a neuralgia.

CASE 12 (reported by Ducastaing)—Male, age unstated. Grenade wound of the thigh. The foot was cold, insensitive, and could not be moved. The patient was in shock. Ten

hours after injury, wound excision was performed in Scarpa's triangle. No pulse was present in the femoral artery, the sheath of which was opened. After hot serum irrigation the pulse was palpable. General condition did not improve and the patient died.

CASE 13 (reported by Ducastaing)—Male, age unstated. Received a grenade wound of the lower third of the upper arm with a fracture of the humerus. Radial pulse was absent. Operated on thirteen hours after injury. The vessel wall was intact. Foreign body removed. Artery irrigated with hot serum and almost instantly pulsation began. Recovered.

CASE 14 (reported by Ducastaing)—Male, age unstated. Received a grenade wound of the inner portion of the lower third of the thigh. Operation ten hours after injury. The popliteal artery was intact and not pulsating. After serum irrigation the pulse was present. Recovered.

CASE 15 (reported by Ducastaing)—Male, age unstated. Patient received a bullet wound of the inner side of the left upper arm. Tourniquet had been applied for six hours. Operated on eight hours after injury. Large hematoma present. No pulsation in the brachial artery but when the muscular branches of the artery were incised there was continuous bleeding. Artery was ligated with hot serum and pulsation returned. Recovered.

CASE 16 (reported by Maury and Daban²⁷)—Man, aged 33. Small grenade wound of posterior median side of lower part of the right upper arm. Humerus was fractured. At open operation the brachial artery pulsed and had a normal caliber in the upper wound but distally a segment 3 cm was filiform. In the contracted region the artery was hard. Artery not incised or disturbed. Recovered.

CASE 17 (reported by Soubeyran)—Male, age unstated. Had multiple grenade wounds of the extremities, but a wound of the right external malleolus was of special interest. At open operation a small projectile was found behind the achilles tendon and the posterior tibial artery was found contracted. Hot serum irrigation did not cause a return of circulation and 3 cm of artery was resected. No thrombus was present in the resected portion but two tiny openings were found in the artery wall. Recovered.

CASE 18 (reported by Abadie²⁷)—Details unstated.

CASE 19 (reported by Delbet²⁸)—Details unstated.

CASE 20 (reported by Tuffier²⁹)—Female, aged unstated. Spasm of the radial artery resulted from opening the artery for a transfusion. No special treatment employed. Recovered.

CASE 21 (reported by von Kuttner and Baruch)—Male, age unstated. Injured by a hand grenade. Had a marked hemorrhage and was in shock. Multiple injuries of the lower extremities and buttock. Operated on four hours after the injury under ether. Posterior tibial artery found contracted and 2.5 cm of the artery was resected. The resected portion was found to be normal and no thrombosis was present. Recovered.

CASE 22 (reported by von Kuttner and Baruch)—Male, age unstated. Grenade wound of the upper leg. The leg was livid in color but voluntary motion was present. Under ether anesthesia five hours after injury it was found that the femoral artery did not pulsate and was contracted a distance of 2.5 cm. Three hours after operation the pulse was normal but again disappeared, then appeared and disappeared again and finally became normal. Recovered.

CASE 23 (reported by von Kuttner and Baruch)—Male, age unstated. Grenade wound of the arm and numerous other places on the body. The brachial artery was spastic. The median nerve was lacerated. The artery was exposed but not operated on and the following day the pulse was normal. Recovered.

CASE 24 (reported by von Kuttner and Baruch)—Male, age unstated. Bullet wound of the left upper arm. Radial pulse

absent Open operation Brachial artery exposed but not operated on Recovered.

CASE 25 (reported by von Kuttner and Baruch)—Sex and age unstated Machine gun injury of the knee region. There were symptoms of arterial occlusion and the popliteal artery was thought to be in spasm The leg was not operated on but was conservatively treated by elevation and warm dressings Recovered

CASE 26 (reported by von Kuttner and Baruch)—Sex and age unstated Bullet wound of the upper leg Pulse absent in the dorsalis pedis and tibialis posterior Patient in shock. The leg was not operated on but was treated by elevation of the leg and a Volkmann's splint Recovered

CASE 27 (reported by von Kuttner and Baruch)—Male, age unstated Grenade wound of the right knee region Beginning gangrene after sixteen hours Popliteal artery was involved in spasm and an amputation was performed at the knee To his (Baruch's) great surprise, the artery, vein, and nerve were intact Final result unstated

CASE 28 (reported by von Kuttner and Baruch)—Male, age unstated Wounded by an infantry bullet in the region of the right sternocleidomastoideus Operated on six hours after injury and the carotid artery had a collar-like spastic area 3 cm long, the size of a goose quill Recovered

CASE 29 (reported by Reichle)—Young man Sustained a fractured femur in a railroad accident Right femoral artery exposed without further operative procedure Recovered

CASE 30 (reported by Reichle)—Male, age unstated. Had a gunshot wound which fractured the femur At operation a waistlike narrowing of the femoral artery was seen Gangrene of the leg and amputation followed Final result unstated.

CASE 31 (reported by Gallo and Calcagno³⁰)—Boy, aged 8 years Fell on left elbow, fracturing the humerus Operative exposure of the brachial artery Artery punctured with needle and serum injected into the artery Recovered

CASE 32 (reported by Winterstein)—Man, aged 54 Fell 3 meters Brachial artery spastic. Treated conservatively without operation Recovered

CASE 33 (reported by Winterstein)—Girl, aged 10 years Run over by an automobile. At open operation the femoral artery was incised and then sutured Recovered

CASE 34 (reported by Winterstein)—Man, aged 43 Was kicked by a horse Operative exposure of the external iliac artery showed it to be in segmentary spasm Artery not incised Treated by elevation of the leg Recovered

CASE 35 (reported by Frassi³¹)—Male, age unstated Grenade wound of the right popliteal region Lost all feeling from the knee down, soon after the injury Under ether anesthesia the popliteal artery was exposed and found to be in spasm On massage of the artery pulsation returned Gangrene of the leg followed, with amputation at the middle third of the thigh Recovered

CASE 36 (reported by Frassi)—Male, age unstated Injured by a bomb explosion causing multiple wounds of the face and ocular bulbs, fracture of the right radius and tibia, and articular lesion of the right knee. Radial pulse was absent At open operation the brachial artery was found to be spastic. Massage of the artery and irrigation with dilute solution of sodium hypochlorite failed to cause a return of pulsation Suppuration of the forearm occurred, necessitating amputation of the arm at its middle third Final result unstated

CASE 37 (reported by Finaly)—Woman, aged 19 Revolver shot of the right upper leg The pulse distal to the wound was absent for twenty-four hours and the femoral artery was spastic The bullet was removed at operation, but the femoral artery was not disturbed. Recovered

CASE 38 (reported by Finaly)—Youth, aged 19 years, a mine worker Received a lacerated wound of the upper leg The pulse distal to the wound was absent Femoral artery involved in spasm Gangrene of the leg extending above the knee required amputation Final result unstated

CASE 39 (reported by Finaly)—Youth, aged 17 years, a mine worker Received a wound of the right leg and abdomen with tearing of the bowel as the result of being crushed between two mine wagons Intestine resected. Femoral artery thought to be involved in spasm but leg not operated on. Toes became gangrenous Final result unstated

CASE 40 (reported by Farani)—Sex and age unstated Open fracture of the femur with partial crushing of the soft parts of the inferior third of the thigh Pulsations of the foot and tibial regions absent After careful examination of the injured region the author was convinced that there were no actual lesions of the tibial vessels Conservatively treated Recovered

CASE 41 (reported by Farani)—Sex and age unstated. Had an abdominal traumatism and gunshot wound of the upper third of the arm The radial artery did not pulsate. The distal arm showed a temperature lower than its fellow The author was convinced that there was no important arterial lesion and that the brachial artery was involved in spasm. Arm immobilized only Recovered.

CASE 42 (reported by Farani)—Sex and age unstated Had a comminuted fracture of the lower third of the forearm with crushed soft parts Radial pulse absent after the fracture. The author took the risk of thinking that there was no arterial lesion and treated the case without operation and he merely treated it as an open fracture Recovered

122 South Michigan Avenue

A NEW AMPUTATION IN THE LOWER THIRD OF THE THIGH

C. LATIMER CALLANDER, M.D.
SAN FRANCISCO

This description of an amputation through the distal extremity of the femur records a sufficient number of novel features to justify its report as a new operation

The essential details of the operation in summary are as follows The anterior flap includes the soft tissues of the upper part of the leg as far as the level of the tibial tuberosity, while the posterior flap is a little longer and extends well down on the gastrocnemius muscle The popliteal vessels and nerves are ligated through an amuscular and avascular cleavage plane on the medial aspect of the low thigh All the hamstring muscles are severed at their tendinous insertions on the tibia, and the femur is sectioned in the condylar flare, just proximal to the adductor tubercle The patella is dissected from the anterior flap from the joint side, leaving the rectus femoris tendon in the floor of the patellar fossa to act as an end-bearing buffer for the femur No coapting primary sutures are used throughout the operation save four to six skin clips or sutures, which hold the flaps roughly in position As the edges of the flaps unite, the posterior flap retracts gradually but very extensively until the femur occupies the patellar fossa snugly, and the suture line is located well up behind the stump end

The advantages this operation offers over other lower third thigh amputations, including the Gritti-Stokes operation, and the simplicity of the procedure warrant a detailed description of the operative technique and an analysis of the results thus far obtained

After the operation has been described in detail, a number of considerations of major interest in amputations in the lower third of the femur in general will be taken up Features of this operation will be con-

trasted with those of the routine amputations of the thigh near this level, and an attempt will be made to evaluate the differences evident from this contrast

DESCRIPTION OF OPERATION

The diagrams illustrate the stages of this amputation in the lower left thigh. The patient is placed in the

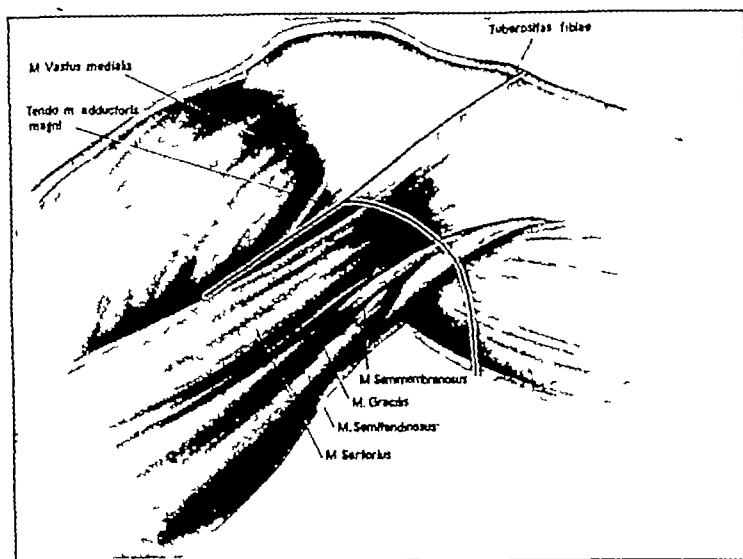

Fig. 1—Medial surface of left thigh and knee. Skin incisions on medial side of the low thigh and knee marking long anterior and posterior flaps. Attention is directed to the amuscular and avascular interspace between the vastus medialis and sartorius muscles. Note that the flaps for this low thigh amputation are derived from the soft parts of the leg.

dorsal decubitus position, the knee of the diseased extremity is flexed slightly, and the leg is elevated a little above the horizontal on one or two sandbags. No tourniquet is applied. The surgeon stands on the side opposite the affected extremity and faces the medial aspect of the thigh and knee to be operated on. He maintains this position throughout the operation because the essential steps are directed through a medial approach to the popliteal space. From this position the operative work on the lateral part of the low thigh and knee are accomplished readily by rotating the knee medially.

The skin incisions (figs 1 and 2) outlining the slightly unequal anterior and posterior flaps are at the same level as the incisions that sever all the deeper soft parts. The incision on the medial aspect of the thigh begins at a point three fingerbreadths proximal to the most prominent part of the medial femoral condyle (fig 1) and runs horizontally distally in the palpable groove between the vastus medialis and the sartorius muscles. With the knee in partial flexion this groove can be defined readily. After the incision has been deepened to the enveloping or deep fascia of the thigh the adductor tubercle of the medial femoral condyle and the tendon of the adductor magnus muscle, which inserts on it, can be palpated. The skin incision continues distally over the medial epicondyle, sweeps forward and crosses the anterior surface of the tibia at the anterior tibial tuberosity, the point of insertion of the quadriceps extensor tendon.

The thigh then is rotated medially (1 e., toward the surgeon). The skin incision on the lateral aspect of the leg, as outlined in figure 2, begins at a point three fingerbreadths proximal to the lateral femoral condyle in the palpable groove between the tendon of the tensor fasciae latae (iliotibial tract) and the biceps femoris muscles. The incision must be made very close to the tensor fasciae latae tendon in order to avoid the muscular fibers of the biceps. Continuing distally over the lateral epicondyle, the incision extends forward to meet the medial incision at the anterior tibial tuberosity, thus outlining the anterior flap of the amputation.

Corresponding incisions from each femoral epicondyle are carried obliquely posteriorly and inferiorly until they meet on the calf of the leg at a point a little inferior to the level of the anterior tibial tuberosity. This incision for the posterior flap is deepened to the fascia on the gastrocnemius muscle. Thus are outlined two long amputation flaps, the posterior a little longer than the anterior. Each flap partakes not only of the soft parts of the lower thigh but of a considerable portion of the soft tissue of the leg.

Attention again is directed to the medial aspect of the thigh and knee (fig 3). The horizontal portion of the medial incision, common to the two flaps, 1 e., that portion lying between the vastus medialis and the sartorius muscles, is deepened through the deep fascia of the thigh. Division of this powerful fascial layer, which is the only strong structure in the medial wall of the popliteal fossa at this level, affords ingress to the popliteal space. The left fore-

Fig. 2—Lateral surface of left thigh and knee. Skin incisions on lateral side of the low thigh and knee marking long anterior and posterior flaps. Attention is directed to the amuscular and avascular interspace between the tendon of the tensor fasciae latae (iliotibial tract) and the biceps muscles. The biceps muscle is composed of fleshy fibers almost down to its insertion on the head of the fibula.

finger, now inserted shallowly into the popliteal space (inset in figure 3), frees the medial hamstring tendons to their tibial insertions by blunt dissection. At this juncture these tendons are divided in the order named: sartorius, gracilis, semimembranosus and semitendinosus. During this dissection, no fleshy portion of any

of the medial hamstring muscles nor any part of the vastus medialis muscle need be exposed, much less severed. The severed hamstring tendons retract at once into the aponeurotic and areolar tissue of the posterior flap and are not dealt with again. Further exposure is gained by severing the tendon of the adductor magnus

contact with the femur as far down as the level of the adductor tubercle in order that there may be as little dead space as possible between the posterior flap and the femur.

The knee then is extended (fig 6) and the incision marking the distal portion of the anterior flap is deepened through the capsule of the knee joint down to the femoral condyles and to the tibia, thereby severing the quadriceps tendon at its insertion into the tibial tuberosity.

The anterior flap containing the patella is dissected upward off the infrapatellar fat pad and drawn upward on the thigh until the superior synovial recesses of the subquadriceps space are seen (fig 7). The patella is dissected from its sesamoid position in the quadriceps tendon, care being taken to preserve the longitudinally disposed tendon of the rectus femoris muscle, which runs over it (inset, figure 7).

The preservation of this tendon adds materially to the end-bearing capacity of the stump after the cut end of the femur is fitted into the socket from which the patella has been removed.

The synovia on the anterior flap and over the femur proximal to the condyles is not excised.

The femur now is sawed through its cancellous portion just proximal to the adductor tubercle (fig 8). At this level the shaft of the femur has expanded to a size that approximately corresponds to the patellar socket in the quadriceps tendon. The cut end of the femur is rounded with a rasp until no sharp surfaces and no fringes of periosteum remain.

muscle at its attachment to the adductor tubercle. Free access to the vasculoneural contents of the popliteal space thus is afforded. Moderate flexion of the knee relaxes the popliteal vessels and nerves and favors their manipulation. With a finger now inserted more deeply into the popliteal space and kept close to the posterior surface of the femur, the popliteal artery and vein are withdrawn easily to a level flush with, or even outside, the skin incision (fig 4). Here they are clamped, ligated, and divided as near the superior apex of the popliteal space as is convenient. The tibial (internal popliteal) and common peroneal nerves then are drawn readily into the wound as one trunk (inset, figure 4) and are anesthetized, ligated and divided. Each of the components of the nerve bundle is injected with absolute alcohol to prevent neuroma formation, and the stump is allowed to retract into the proximal recess of the popliteal space.

The partly flexed knee now is rotated toward the operator (fig 5), and the lateral longitudinal skin incision is deepened through the deep fascia of the thigh. The incision is carried through the deep fascia as far as the insertion of the biceps muscle on the head of the fibula, where the biceps tendon then is severed. At this stage of the operation the popliteal space may be opened widely from side to side since the essential structures have been divided. Deepening of the incision marking the posterior flap down to the gastrocnemius aponeurosis and clearing from it the areolo-adipose debris free the posterior flap. It is advantageous to leave the fibro-areolar tissue of the popliteal space in

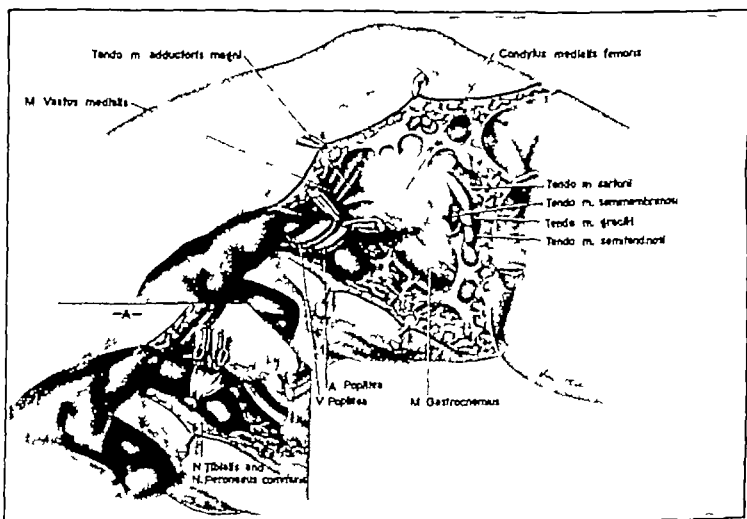

Fig 4—Medial surface of left thigh and knee. Further deepening of the flap incisions on the medial aspect of the knee. The vessels and nerves in the popliteal space are sectioned. The main drawing shows the retraction of hamstring muscles after section at their tendinous insertions on the tibia. The contents of the popliteal space now are widely accessible and the vessels are ligated. The inset demonstrates the method of securing and dividing the tibial and common peroneal nerves.

The two large flaps are inspected now for small bleeding points. These can be ascertained best by sluicing the surfaces of both flaps with large quantities of warm salt solution. This flushing has the additional advantage of washing away small soft tissue and bone

debris. Many small bleeding points may require ligation after this procedure. Inspection of the body of the posterior flap shows no muscle fibers but only areoloidipose tissue and the cut ends of the hamstring tendons. These tendons already are retracted into their aponeurotic beds and are scarcely visible. The flaps

POSTOPERATIVE CONVALESCENCE

After the operation, the stump is wrapped snugly in a gauze roll and the patient is returned to bed. He is able to sit upright in bed in the evening of his operative day and can be placed in a wheel chair during the next day or two. Daily dressings are required because an

abundant serosanguineous oozing between the skin edges may take place for several days in spite of the most meticulous hemostasis. The drainage gradually lessens. The absence of primary suturing, other than that necessary for flap approximation, minimizes the pocketing of fluid accumulation and allows all secretions to escape through the wide intervals between the skin clips. Usually the major oozing stops in from one to three days. When this drainage has ceased, the skin edges between the sutures placed at the time of the operation are approximated carefully by additional skin clips. These clips are applied readily without anesthesia. This procedure, which has been adopted only in the most recent cases, has resulted in complete union of the flap edges within a week. The time of convalescence has been decreased remarkably in this fashion.

As convalescence progresses, the posterior flap retracts gradually until the suture line, now posterior in position, is well proximal to the bone end, occasionally a distance of one or more inches (fig 10). When it is recalled that the suture line at the end of the

operation is an inch or more distal to the bone end, it becomes apparent how extensive is the power of the intact hamstring muscles to retract the posterior flap. In a short time the femur is lodged securely in the patellar fossa, thus assuring great stability to the soft parts of the stump. There is excellent end-bearing because of the presence of the rectus femoris tendon, the elements of the prepatellar bursa, and of tough

Fig 5—Lateral surface of left thigh and knee (knee rotated medially toward surgeon). Deepening of the flap incisions on the lateral aspect of the knee. Left knee forcibly rotated medially. The interval between the iliotibial tract and the biceps muscle is defined and the biceps is sectioned at its insertion on the head of the fibula. The inset indicates the structures deep to the biceps tendon. The common peroneal nerve already has been sectioned through the medial approach (fig 4).

now are allowed to fall together loosely (inset B, figure 8).

The only coapting suturing during the operation is in the form of not more than four to six clips or sutures placed at such intervals as to keep the flaps in fair apposition (fig 9). When the skin edges are approximated, the aponeurotic edges also lie in contact, mere apposition is sufficient to produce firm union. None of the tendons or aponeuroses of the anterior flap are sutured to the corresponding structures of the posterior flap. In this way no structure is under any tension, and the trauma and consequent pressure necroses resulting from suture of these deeper structures therefore cannot occur. The flaps appear exceedingly long and even extend an inch or more beyond the femur end immediately after they are fashioned. To the surgeon accustomed to the routine type of low third femur amputation, the flaps will appear excessively redundant and clumsy, and he will fear that a bulbous stump-end and large dead spaces will result. He will wonder, too, when he notes how wobbly the femur lies between the flaps, how the femur end will gain contact with the patellar socket and fuse there. During the early days of convalescence, the reason for leaving these flaps under no tension appears.

At the end of the second or third postoperative day and sometimes even within a few hours after the operation, the hamstring muscles severed only at their distal attachment contract to the degree that the skin suture line lies posteriorly placed at about the level of the stump-end, and the femur is felt in the patellar fossa.

Fig 6—Anterior surface of left thigh and knee. The incision marking the anterior flap is deepened through the knee joint capsule and infrapatellar tendon down to the tibia.

skin over the bone end. The patient can extend his stump powerfully, a requisite in any thigh amputation.

In this series, healing has taken place in four weeks on the average. In the last three cases, in which the skin edges between the primary suture points were approximated secondarily by additional clips, healing was complete at the end of a week.

ANALYSIS AND COMPARISON OF THE FEATURES OF THIS AMPUTATION WITH THOSE OF THE ROUTINE LOW THIGH AND GRITTI-STOKES AMPUTATIONS

Vascular Considerations—Control of Blood Supply
The common use of a tourniquet of one kind or another in thigh amputation should be limited to the very exceptional case. That the pressure consequent on its

nourish the skin and subcutaneous tissue of the upper leg to a degree sufficient to enable upper leg flaps in this thigh amputation to heal readily. Proof of this occurred in five cases of amputation. The popliteal artery was filled with thrombus, did not bleed on section, and therefore could not have furnished blood to the superficial structures about the knee and the upper leg. Nevertheless, the leg flaps, cut as outlined in figures 1 and 2, contained small spurting vessels in their edges, vessels which were derivatives of the profunda arterial tree. In these cases of obliteration of the popliteal artery, the medial and lateral circumflex branches of the profunda anastomosed with the arterial network about the knee and furnished adequate blood supply to the anterior flap in our amputation. The posterior flap is nourished by the terminals of the perforating system of the profunda. The flaps in each of these five cases united readily into strong stumps with no loss of tissue substance along the suture line. Why it is that the profunda artery and its terminals so often remain permeable in obliterating disease of the superficial femoral artery and its tributaries is not known.

Length of Amputation Flaps—It is common knowledge about the routine types of lower third thigh amputations that the premature contraction upward of the posterior flap, actuated by contraction of the hamstring muscles, is one of the usual causes of infection, a danger often leading to reamputation. Extensive retraction of severed hamstring muscles is to be expected when one realizes that all but a part of one of these muscles arise on the pelvis and span

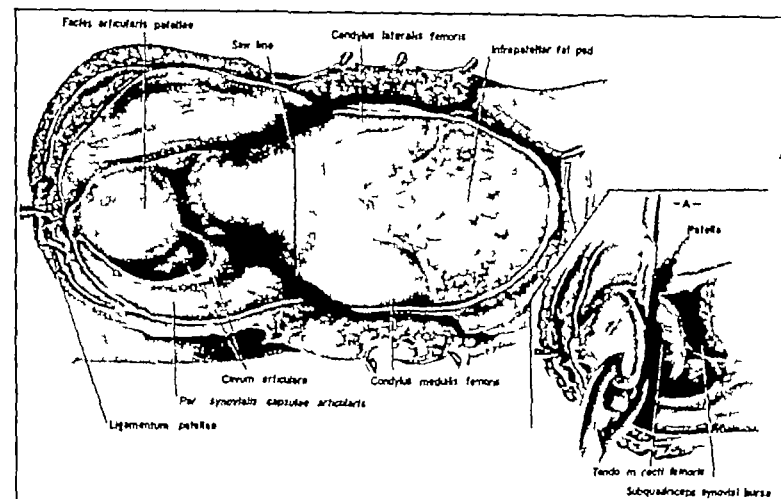

Fig. 7—Anterior surface of left thigh and knee. Upward dissection of the anterior flap and removal of the patella from the joint side. The saw line in the main drawing is well done into the condylar flare. The inset shows the sharp dissection of the patella from its fossa in the quadriceps tendon leaving the rectus femoris tendon intact to act as a buffer for the cut end of the femur.

use may provoke thrombosis in vessels in which none heretofore has been present, and that a greater degree of thrombosis may be caused in a vessel in which a moderate amount already exists, are very real dangers which should contraindicate its use. In altogether too many patients the tourniquet still is advocated and used in the routine type of low thigh and knee amputations.

The common practice of waiting to ligate the popliteal vessels until after any or all of the hamstring muscles are severed in the popliteal space by way of the posterior approach is a clumsy procedure. In addition to the shock attendant on severing large muscles in their fleshy portions, there usually is considerable hemorrhage from their section when the main blood supply as yet has not been controlled. I advocate the medial approach to, and ligation of, the popliteal vessels through the avascular and amuscular space illustrated in figure 4.

Importance of the Profunda Femoris Artery in Regard to the Nourishment of the Amputation Flaps Attention is directed to several points of interest concerning the profunda femoris artery and its terminals. The profunda, practically speaking, is the artery of the tissues of the thigh. With the peripatellar arterial circle, with which it anastomoses, it also can nourish the skin and subcutaneous tissue of the knee and upper part of the leg, certainly for a considerable distance below the joint line. The superficial femoral artery gives off no important branches in the thigh save the *suprema genu* (*anastomotica magna*).

Visual operative evidence repeatedly has demonstrated to me that the profunda artery alone is able to

Fig. 8—Medial surface of left thigh and knee. Section of the femur after formation of long anterior and posterior flaps. Inset A the patella fossa is ready to receive the cut end of the femur. Inset B shows the anterior flap loosely approximated to the posterior flap. As the flaps unite and the posterior flap retracts the patellar fossa lodges the femur end.

a practically uninterrupted arc to their insertion on the tibia. Only the short head of the biceps femoris has its origin on the shaft of the femur.

The components of the quadriceps muscle are the essential retractile elements in the anterior flap. All

these components save the rectus femoris, however, arise from the shaft of the femur through a very considerable portion of its extent. Consequently there is only a short span of muscle unattached to the femur which can exert a pull on the quadriceps tendon, whether that tendon is divided in the suprapatellar area as in the routine tendoplastic amputation or in the infrapatellar portion as in the Gritti-Stokes and my own operations. The tensor fasciae latae muscle with its origin on the iliac crest and the dorsum of the ilium near the anterior superior spine is inserted distal to the level of the greater trochanter into the iliotibial tract, a specialized portion of the fascia lata of the thigh. Severance of this tract proximal or distal to the patella does not result in marked retraction of this aponeurotic unit, mainly because of the short span of the muscle bundle that activates it.

As a result, the anterior flap in any thigh amputation retracts very little, while the posterior may retract to an extraordinary degree. In our amputation the tibial attachments of the hamstring tendons and not the muscle bellies are severed, as a result of which all the hamstring contractile elements are in the posterior flap. Consequently a much greater amount of retraction of this flap occurs than in the routine low thigh and Gritti-Stokes operations, in which the hamstring muscles are divided in their fleshy portions. In order to allow retraction to take place without tension, I fashion the anterior as well as the posterior flap from the skin and subcutaneous tissue of the upper part of the leg.

Stump Length and Weight Bearing—Too often the ordinary amputation in the lower third of the femur results in a bone length inadequate for leverage on a prosthesis. Especially is this true when a secondary amputation is required because at the original operation the flaps, the posterior one particularly, were made too short. Sometimes even during the first amputation the femur has to be resawed at a higher level to allow flap approximation.

I find no fault with the length of the stump in a Gritti-Stokes operation. This procedure, however, is difficult technically and is one in which there often is a poor functional result. It is not a simple matter to remove accurately the cartilage-bearing part of the patella in such a manner as to fit the remainder of this bone snugly against the sawed end of the femur, and there acquire bony union. Any leg maker can relate many instances in which the patella has failed to unite with the femur. Even when the soft parts in the amputation heal, the patella, as the result of nonunion, may wobble somewhat in its position on the femur end or may slide to one side or completely off the end of the bone. Even when bony union between the patella and femur occurs, the irregular shape of the patella often precludes functional end-bearing. When infection occurs in the suture line, a result usually of too much tension from too short a posterior flap, union between patella and femur rarely occurs. In my experience in these cases the patella and often a segment of femur are sacrificed when reamputation is resorted to.

In my amputation the femur is sectioned at a constant level, one just proximal to the adductor tubercle, thus affording a stump length equal to that in a Gritti-Stokes amputation. At this level the femur presents a broad weight-bearing area, which is about double that of the femoral shaft and much greater than that of the patellar extremity of a Gritti-Stokes stump. Since the flaps are exceedingly long, they are adequate to cover this femur length and are under no tension.

Should infection occur, it can be eliminated before contraction of the hamstring muscles has shortened the posterior flap to the extent that a resawing of the femur is required. Reamputation has not been necessary in any of my cases.

The patellar socket gradually lodges the femur end in the amputation I have described. Union between the femur end and the rectus femoris tendon, which floors the patellar socket, soon becomes firm and painless. There is no such accuracy of apposition demanded between opposed structures as in the Gritti-Stokes operation, and infection does not vitiate the result.

The classic lower third femur amputation stump often is not end bearing, but the properly made Gritti-Stokes stump sometimes is. The stump in my operation bears weight directly because of its broad bearing surface and the substantial fibrous coverings afforded the femur end. The femur fits closely in the patellar

Fig 9—Transparency drawings to show the location and size of the condylar end of the femur in the redundant amputation stump. A is a view of the stump from the front. B is the stump seen from the side. C is the stump viewed from the end before the clips have been placed. The skin clips are the only means of approximating the flaps at the time of operation.

socket against the tendon of the rectus femoris muscle. In addition, the prepatellar bursa and the thick skin over the knee are well adapted to pressure.

The stump in the amputation I am describing and that in the Gritti-Stokes procedure have an important feature in common. This is the slightly bulbous stump end, the result of sectioning the femur within the flare of the condyles. The distal flare of the resulting stump allows the leg maker to fit a prosthesis, the thigh cuff of which grasps the stump above the condylar flare and keeps out loose motion in lifting the leg and moving it backward and forward.

Pyogenic Wound Infection—Most infections in routine lower third and Gritti-Stokes amputation stumps are the result of too great a tension on the suture line. This is caused by making the posterior flap too short. I believe that a posterior flap cut in the popliteal space usually is too short to allow attachment to the anterior flap without considerable tension. If the femur is sec-

tioned in the upper part of its lower third, tendino-muscular flaps can be cut sufficiently long to cover the bone end without serious tension. This does not mean, however, that in the course of the first few post-operative days the suture line in certain instances will not be under sufficient strain to result in necrosis and subsequent infection. This, from a knowledge of the amount of retraction that takes place in the posterior flap in my operation, must occur when the lower limit of the posterior flap extends only to the middle of the popliteal space, as so many illustrations of this operation indicate. I have seen failures to heal on this account in my series of Gritti-Stokes cases. Infection following tension necrosis at the suture line is propagated to the severed fleshy parts of the hamstring muscles. Extensive infection often necessitates a frank open reamputation. When infection occurs in the Gritti-Stokes operation, not only the patella but often a segment of the femur must be sacrificed.

Fig. 10—Anterior posterior and close-up views of amputation stump. The suture line is placed well proximal to the stump end. This patient is now able to walk with a full end bearing prosthesis.

In the usual lower third femur amputations, large *en masse* sutures frequently are used to approximate the flaps. These ligations predispose to necrosis of the included tissue. Dead spaces with no access to the outside may be created, in these spaces, infection often develops. From these infected closed spaces, pus may extend up the connective tissue spaces and muscle bundles of the posterior thigh more readily than out through the tightly closed suture line or through paths created by drains. Drainage material plunged into the depths of the amputation cavity created by suture of the flaps may lead to infection in the deeper tissues.

In my operation, every precaution is taken to insure against infection. First, the posterior flap is cut so long that tension between it and the anterior flap cannot exist. Only late in convalescence is there any tension whatever on the line of union between the two flaps. One of the greatest safeguards against infection in the stump itself and to propagation of infection up the thigh is the section of the hamstring muscles at their tendinous insertions on the tibia. By operating through natural intermuscular cleavage spaces, no hamstring muscle fibers are seen or sectioned. This is equally true of the quadriceps muscle, which is sectioned in its

infrapatellar tendinous portion. The fleshy muscle bellies and their tendons proximal to the point of section thus maintain their normal anatomic relations. They remain surrounded and protected by the enveloping deep fascia of the thigh and popliteal space and by the fibrous inward prolongations from this parent aponeurosis. It is difficult to see how infection can extend up the thigh under these circumstances. Anatomically the popliteal space is a closed cavity, there being no communication with the upper part of the thigh through the vascular ring in the adductor magnus muscle. Since no hamstring muscle belly has been cut in this operation, no muscle planes are left open for upward extension of infection. The anterior flap is not dissected proximally enough to expose muscle bundles. Leaving the synovia on the under surface of the anterior flap and in the subquadriceps bursa interposes a barrier to the upward extension of infection. Removal of the patella after the anterior flap has been turned upward exposes no muscle fibers to infection. In my operation, no area of skin and subcutaneous tissue is dissected from the deep fascia. This insures against the spread of infection up artificial planes.

Another unique safeguard against infection is the absence of suture tension on any structure in the amputation stump. A few skin clips, placed at widely spaced intervals at the cut edges of the flaps, are the only means of flap approximation at the time of operation. Mere contact without suture suffices for union of the aponeurotic elements. The wide intervals in the skin edges left between clips are adequate for the free drainage of tissue juices. The exudation of blood-stained serum may be copious for the first few postoperative days, but it diminishes gradually as convalescence goes on. This postoperative oozing of serum is a safeguard against infection which otherwise might result from contamination of loculated fluid collections. The placing of additional clips between the clips used at the time of operation in order to get better skin approximation is not done until the postoperative oozing has stopped and until it is demonstrated that infection has not taken place.

Gas Bacillus Infection.—In our service in the San Francisco Hospital up to the time of the development of the amputation here described, gas bacillus infection has occurred in thigh amputation stumps of eleven patients out of sixty operated on for arteriosclerotic gangrene. Ten out of eleven of these patients died. Gas bacillus infection occurred seven times in the thigh amputation stumps of thirty-one patients operated on for diabetic gangrene. Five of these patients died. This infection has occurred eighteen times in the stumps of forty-six patients who had thigh amputations for gas bacillus infection in compound fractures and severe lacerations below the knee. Twelve of the eighteen patients died.

Reflection as to the cause of the development of gas bacillus infection in thigh amputation stumps was an important factor leading up to the elaboration of the amputation technic under discussion. The predilection of gas bacilli for muscle tissue, the longitudinal spread of infection up individual muscles and groups of muscles, and the growth of these organisms in the absence

of oxygen are observations too frequently made to be incorrect. In gas bacillus infection it is noteworthy that aponeurotic, tendinous and subcutaneous structures are spared early and sometimes even late in the disease.

As a result of these observations, it seemed that an amputation which would expose no thigh muscles to actual contamination, save in their tendinous insertions, would lessen the probability of complicating gas bacillus disease. In addition, the ideal amputation should have the added feature of being able to be left open. The necessity for open amputation is required when the operation is performed close to the site of infection. By this procedure, anaerobic conditions in the stump are avoided and the danger of upward spread of infection from distal foci is minimized. In the operation under discussion, the flaps are of sufficient length to allow the wound to be packed open over a period of time if necessary without their retracting to a degree that makes later closure by simple approximation impossible.

Recumbent Convalescent Period—In the routine low thigh and Gritti-Stokes amputations, tissues often are on such a degree of tension that it becomes necessary to apply skin traction to relieve the suture line. Skin traction may relieve tension on the skin suture line but has little or no effect on the tautness of the aponeurotic line of closure. Movement of a stump under tension is painful and requires recumbency for a period of days. The patients with our thigh amputation never require skin traction and are able to sit up in bed on the day of their operation and be in a wheel chair the day following amputation. Since there is no tension on the elements of the stump, free movement is comparatively painless. Danger of pneumonia from enforced recumbency is lessened materially.

Operative Shock—Shock from bleeding and from section of the hamstring muscle bellies has occurred in many cases of routine thigh amputation. There is very little intra-operative or postoperative shock from the operation I am describing. This lack of shock I attribute to two factors: control of hemorrhage by early ligation of the popliteal vessels and the severing of muscles only in their tendinous insertions.

Mortality—Mortality from thigh amputation will be decreased very considerably if the technic as outlined is followed meticulously. The factors that lower the mortality rate are: lessened shock from adequate control of blood supply and from section of muscles only in their tendinous insertions, diminished incidence of pneumonia from a lessened period of recumbency, decreased tendency to anaerobic or aerobic infection because no structures are under tension, this being the result of long flaps and little suturing, ready exit for the serum produced in the wound, and the lessened incidence of reamputation, which in itself carries a considerable death rate.

Thus far fourteen amputations have been performed according to this method. The majority of these patients were over 70 years of age. One has died, a mortality of about 7 per cent. This man was 84 years of age and died eleven days after his operation from a coincidental pneumonia. His amputation was the second in the series and at the time of his operation I did not know that I could get the patients up almost immediately. It is likely that his pneumonia could have been averted by the process of getting him into a wheel chair on the second postoperative day, the procedure I adopted in all later cases. His amputation

wound was fairly clean and had united partially. In thirteen of these fourteen cases amputation was done for arteriosclerotic or for diabetic gangrene. One amputation was done for intractable compound fracture near the knee.

Mortality statistics of thigh amputations vary widely. Much depends on the condition of the patient. The best of the larger series show a death rate of 15 per cent, while the series in the city hospitals and relief homes show much higher figures. Prior to the development of this operation, the mortality of thigh amputations in our service in the San Francisco City Hospital exceeded 50 per cent.

COMMUNUTED COLLES' FRACTURES IN ELDERLY PATIENTS

METHODS OF TREATMENT AND END RESULTS IN THIRTY CASES

G E HAGGART, MD
BOSTON

The treatment of uncomplicated Colles' fracture is now well recognized. While the methods employed by different operators reveal many variations in procedure, the underlying principles are quite similar. However, in comminuted Colles' fracture, especially when occurring in elderly patients, it is believed that the results

Fig. 1—Sugar tong plaster splint removed from arm (reprinted from *New England Journal of Medicine*.)

Fig. 2 (case 2)—Appearance of 'sugar tong' plaster splint applied.

can be greatly improved, particularly by longer splintage than is usually employed, and also by attention to certain details as herein described. In a previous communication a method of treatment for this fracture was presented with particular emphasis on the duration of splintage, which in these older patients averaged six

weeks as compared with a total of from two to three weeks for similar injuries in younger adults

The present paper is a report of the results obtained in the treatment of thirty elderly patients, aged from 58 to 70, with comminuted Colles' fracture. To illustrate the significance of prolonged splintage, properly applied, as well as the importance of fracture observa-

ticularly prone to occur at the dorsal fracture line in the radius where the distal dorsal end of the proximal radial fragment tends to absorb. Hence, bone repair is often so far from complete that following the usual time of splintage—that is, from two to three weeks—a partial to complete recurrence of the deformity takes place on resumption of the use of the hand, notably the act of dorsiflexion.

3 It is often necessary to hold the hand in palmar flexion and ulnar deviation in order to prevent displacement of the comminuted radial fragments. Fluoroscopic vision of the fracture will determine whether this

position is indicated. To maintenance of this flexed wrist position is ascribed the occurrence of flexor muscle contracture following removal of the splint. This complication was not observed in the cases in group 2, for, with the fracture well healed and fol-

Fig 3 (case 2)—Roentgen appearance on admission of comminuted Colles fracture in woman aged 68. Observe marked displacement of radio-ulnar joint

tion under the fluoroscope, these thirty cases are divided into two groups: group 1, fifteen cases in which posterior or anterior and posterior forearm splints were applied for an average of three and a half weeks; group 2, fifteen cases wherein the fracture was completely immobilized by means of the sugar tong plaster splint for an average of six weeks. All fractures in the latter group were reduced and the position then checked by fluoroscopic vision. The results in the second group of cases were definitely better than those in group 1, as shown in the accompanying table.

A survey of these cases indicates that comminuted Colles' fracture in elderly patients should be treated as a distinct group compared with similar fractures in younger adults. The following observations are significant:

1 Owing to the relatively brittle avascular bones of elderly individuals, comminution of fragments is more frequently observed at the time of reduction. Such comminution may not be evident in a preoperative roentgenogram.

2 Bony union in these patients is delayed as compared with the same fracture in younger adults. In some elderly patients complete bone repair may not occur even though the fracture is perfectly reduced. Magnuson¹ believes that this is due to disintegration of bone cells at the end of each fragment with consequent loss of bone substance. Delay in healing is par-

Fig 4 (case 2)—Roentgen appearance one year and three months after admission. Normal finger and wrist motion.

lowing the institution of active exercises and intensive massage, all patients in this group rapidly regained active dorsiflexion of the hand. In three patients of group 1, who were splinted an average of three and a half weeks, and in one patient splinted five weeks, the return of function at the wrist was impaired because of partial recurrence of the deformity owing to resumption of active motion when bone repair was not complete.

4 To secure satisfactory alignment in these comminuted fractures and to determine the most favorable position in which to hold the fragments, reduction under the fluoroscope is particularly helpful. Such visualization of the fracture is indeed essential to decide whether palmar flexion of the hand is necessary for holding the fragments. Since the adoption of this technic for all cases of comminuted radial fractures (group 2 cases), the average amount of palmar flexion of the hand has been between 10 and 20 degrees. In

Fig 5—Molding radial fragments into alignment, traction maintained after first breaking up impaction by manipulation (reprinted from New England Journal of Medicine²)

six cases the hand was placed in the midposition, as under the fluoroscope the fragments were found to remain in excellent alignment. Obviously with this relatively slight degree of wrist flexion muscle contraction is not prone to occur, even though the part is splinted an average of six weeks.

TECHNIC OF REDUCTION OF COMMINUTED COLLES' FRACTURES

The following procedure was employed in all the group 2 cases and in six of the patients classified in group 1. This technic is the method now utilized at the Lahey Clinic in reduction of all Colles' fractures.

Anesthesia—These fractures are most satisfactorily reduced under a general anesthetic. In our hands, local anesthesia for comminuted Colles' fractures has not been satisfactory. Blocking of nerve trunks with procaine hydrochloride at the elbow or shoulder may be considered if general narcosis is contraindicated.

At the present time these elderly patients are given either tribrom-ethanol anesthesia, an average of 70 mg per kilogram of body weight, or, in cases in which a rapid uncomplicated reduction is anticipated, intravenous N-methyl-cyclohexenylmethylmalonylurea sodium is employed. Reinforcement with nitrous oxide (ethylene is not used in the fluoroscopic room) is rarely necessary with tribrom-ethanol but may be indicated following N-methyl-cyclohexenylmethylmalonylurea. Tribrom-ethanol anesthesia has been particularly satisfactory because of the adequate relaxation, absence of postoperative nausea and vomiting, and the fact that in the dark fluoroscopy room omission of anesthesia apparatus is appreciated.

Reduction—A wide strap or band is passed about the midarm and tied to the table, thus furnishes a fixed point against which the operator can maintain steady traction and yet have complete control of the hands, wrists and forearm. Impaction of the radial fragments is first broken up by manipulation and then, with traction maintained the fragments are molded into alignment by firm pressure of the operator's thumb passing distally over the dorsum of the patient's wrist (fig 5). This maneuver brings the patient's hand into volar flexion, thus fixing the reduced radial fragments in position. If necessary, the fragments are aligned by slight ulnar deviation of the hand.

Fluoroscopic observation of the reduction is obtained as indicated. It is particularly helpful in checking the anatomic relations of the radiocarpal and distal radioulnar joints. To determine the position of the hand that best maintains the alignment of the fragments and to make certain of resumption of a normal joint relationship, fluoroscopic vision is essential. With this position decided on, it is then held by the operator, and an assistant applies the "sugar tong" plaster splint.

Splint—The "sugar tong" plaster splint (fig 1) originally devised by Simpson, is one of the most efficient and at the same time simplest appliances that can be utilized in fractures of the forearm. The splint consists of a plaster-of-paris bandage reverse, covered on one side by cotton flannel. The length of the splint is determined by the distance from the knuckles up the dorsal forearm, around the elbow and down the volar surface of the forearm, to the base of the fingers. Trimmed at the wrist so that the plaster edges will not overlap and cut out over the thenar eminence, the splint, after having been well rubbed but while still moist, is applied to the elbow, forearm, wrist and hand and bandaged snugly in place with a gauze bandage (fig 2).

It is particularly important to note that the respective ends of the plaster terminate at the knuckles on the dorsum and just proximal to the base of the fingers on the volar surface of the hand (fig 6). When properly applied, this splint permits the patient complete normal range of flexion-extension in all the interphalangeal and metacarpophalangeal joints. In addition to anterior-posterior immobilization of the radius and ulna, by passing around the elbow the splint also prevents pronation and supination, an especially important stabilization when dealing with a comminuted Colles' fracture.

Fig 6—To illustrate correct method of application of "sugar tong" plaster splint. Normal range of motion in the interphalangeal and metacarpophalangeal joints, elbow joint from 30 to 40 degrees of flexion-extension, absence of pronation or supination of forearm is essential to prevent displacement of comminuted radial fragments.

Motion of the elbow is not completely limited, as the appliance permits an average total range of from 30 to 40 degrees of flexion-extension of the elbow joints.

In these comminuted fractures in elderly people, still further swelling of the soft parts nearly always occurs after the manipulation and reduction of the fracture.

This is particularly true if some time has elapsed before treatment is instituted. If circulatory interference develops as indicated by the presence of pain and edema of the fingers, the gauze bandage is cut between the two arms of the splint and a fresh bandage put on without disturbing the previous one. Once the swelling begins to subside, the gauze bandage is again cut and, with the splint firmly held by an assistant, another bandage is snugly applied. By these maneuvers the circulation of the hand and forearm is controlled and yet no disturbance results in the alignment of the bone fragments.

Postoperative Course—After roentgenograms confirm a satisfactory position of the fragments and show the restoration of normal radiocarpal and distal radio-ulnar joint relationship, the patients are instructed first to use the fingers constantly not only to move the joints actively through their maximum range fifty times daily but at all times to employ the fingers as nearly as possible as in normal daily use, secondly, to abduct the entire arm over the head a minimum of six to eight times a day. The latter exercise prevents loss of shoulder joint function, which is so prone to occur if the arm is held constantly at the side of the body. Impairment of shoulder joint motion is particularly apt to follow Colles' fracture, since falls on the outstretched hand frequently cause trauma to the tendon of the supraspinatus muscle and to the subacromial bursa.

Removal of the Splint—It is my belief that in these comminuted Colles' fractures the best results are secured by maintaining the original position and splint a minimum of from five to seven weeks. In the group 2 cases the average was six weeks. This is directly contrary to my treatment of uncomplicated Colles' fractures in younger adults, in which the bandage is cut down in from seven to ten days, with the dorsal "tong" sprung open and early massage instituted. In young people, active motion can be allowed in from ten days to two weeks and all splintage removed in from two to three weeks.

In the fifteen patients classified under group 2, the foregoing plan was carried out with the result that in each instance the patient secured union of the fragments in the position in which they were placed at the time of the reduction. None of these patients had flexion contractures of the muscles of the forearm. All presented a range of motion in the finger joints equal to that present before the fracture, and in six instances this range of motion in the fingers had been appreciably increased. In this connection it is believed that, regardless of the degree of arthritic change already present in the interphalangeal joints, fracture of the radius need not and should not be a factor in further progression of this very disabling arthritis.

The decision was reached to splint these patients an average time of six weeks, following the observation that patients did not develop contractures of the flexor group of muscles of the forearm, and because a dorsal tilt of the articular surface of the radius recurred in patients splinted as long as four and in one instance five weeks. The history of the latter individual is particularly instructive (case 1). These data may be compared with those of case 2, in which splinting was maintained for six weeks.

CASE 1—A woman, aged 70, unmarried, was admitted to the clinic three hours after a heavy fall down steps, striking on the outstretched hand with resulting complete disability of the affected extremity. The extensive comminution later found on manipulation was not evident in the roentgenograms.

Reduction was performed and checked under the fluoroscope. Normal anatomic relationship of the radiocarpal and distal radio-ulnar joints and normal alignment of radial fragments resulted. After five weeks, further roentgen study revealed maintenance of reduction and showed evidence of new bone proliferation. The splint was removed and massage and active exercises were instituted. The range of motion at the wrist progressively increased. The patient had no symptoms and in the eight weeks after operation declared that she had a normal hand and wrist joint. Examination revealed volar flexion of the hand to a right angle. Dorsiflexion was 60 degrees (now increased to 90 degrees one year after injury). Radial and ulnar flexions were normal as compared with the noninjured side. Forearm pronation was normal, supination within 10 degrees of normal (still lacks 5 degrees of complete supination). Roentgenograms at this time, however, revealed a partial recurrence of the original deformity, although, fortunately, there was no tilt of the radial articular surface.

Comment—A good functional, moderate anatomic wrist resulted in the patient, who was poorly muscled and anemic. It is believed that the anatomic result would have been better had the splint been left on from six to seven, instead of five, weeks. Compare with

CASE 2—Mrs. M. M., aged 68, a housewife, was admitted to the clinic, Feb. 13, 1934, two hours after a heavy fall on the outstretched right hand. Figure 3 was taken on admission and revealed a comminuted fracture of the radius, with posterior displacement and rotation of the distal fragment. There was dislocation of the radio-ulnar joint. Marked comminution was evident at the time of reduction. Figure 2 shows the arm in the "sugar tong" plaster splint. A check up roentgenogram (fig. 4) was taken May 20, 1935, one year and three months following injury. On clinical examination the patient had normal motion in all directions at the wrist and of the fingers.

When the procedure described was instituted three years ago I² was unaware that Platt³ of Manchester, England, had advised five weeks of immobilization for Colles' fracture with displacement. In other papers consulted the average duration of splintage was from three to three and one-half weeks. It is believed that in the type of case here reported immobilization should average six weeks, but that in younger adults with "displaced" Colles' fracture an average of from three to four weeks in splints is sufficient.

TREATMENT OF DISABLING, OLD, UNREDUCED COLLES' FRACTURE

The comparatively excellent results obtained in these difficult cases through the simple operation described by Darrach,⁴ has not been sufficiently recognized. Symptoms are chiefly due to the disturbance in relationship of the distal radio-ulnar joint. A traumatic arthritis develops and with weakness of the wrist causes marked disability. Darrach advises subperiosteal resection of the lower 3 or 4 cm. of ulna. The styloid process is not removed.

I have operated on three such patients admitted to the clinic one year, ten months and eight months, respectively, following fracture. The results were most satisfactory.

SUMMARY

1 Comminuted Colles' fractures are of relatively frequent occurrence in elderly patients. The comminution appears to be due to the presence of brittle avascular bone.

2 Prompt reduction of the fracture is imperative.

3 Reduction should be carried out under general anesthesia, tribrom-ethanol preferred, and then visualized under the fluoroscope.

² Haggart, G. E. The Treatment of Comminuted Colles' Fracture in Elderly Patients. *New England J. Med.* 209: 1140 (Dec. 7) 1933.
³ Platt, Harry. Colles' Fracture. *Brit. M. J.* 2: 288 (Aug. 13) 1932.
⁴ Darrach, William. Fractures of the Lower Extremity of the Radius. *J. A. M. A.* 89: 1683 (Nov. 12) 1927.

4 It is most important that the dorsal tilt of the radial articular surface be corrected and that the normal relationship of the distal radial ulnar joint be reestablished

5 There are pronounced advantages of the so-called sugar tong (Simpson) plaster splint

6 Because of the tendency to recurrence of the deformity of the distal end of the radius in these elderly patients, owing to delayed bone repair, it is believed that the extremity should be continuously immobilized in the "sugar tong" plaster splint for a minimum of from five to seven weeks. The splint is adjusted as indicated, unless there originally was marked swelling, this adjustment does not require removal of the splint

7 Flexion contracture of the hand did not occur in the patients treated by this method

8 Free finger joint motion is necessary, a range of motion allowed by careful application of the splint. Daily complete arm abduction is of advantage in avoiding limitation of shoulder joint motion

9 Nonunion of the ulnar styloid, following fracture, was not a significant cause of symptoms

10 With this procedure, followed by intensive massage, heat and active exercise, a good anatomic and a good functional result was obtained in twelve and in ten patients, respectively, in a group of fifteen (group 2) as compared with five good anatomic and six good functional results in a similar group of fifteen patients (group 1) who were splinted an average of three and a half weeks

605 Commonwealth Avenue.

ABSTRACT OF DISCUSSION

DR. W. BARNETT OWEN, Louisville, Ky. Comminuted Colles' fractures in old people have been the source of much worry to the surgeon and pain and disability to the patient. All have seen the type of case following a Colles' fracture, in which loss of function, swelling of the fingers and painful motion of the wrist have occurred. In a very large proportion of cases a deformity has resulted from absorption of the distal fragments of the radius. However, many times, when some deformity of the wrist has resulted, there has been good restoration of function of the hand and arm. Dr. Haggart's conclusion that it is most important that the dorsal tilt of the radial articular surface be corrected and that the normal relationship of the distal radio-ulnar joint be reestablished is one of the most important statements he has made. To produce this situation, it is obvious that the proper reduction of the fracture primarily, must be accomplished. It has been my custom to place the wrist in palmar flexion after reduction and to apply a dorsal splint of plaster, usually a nonpadded cast is to be preferred. The gripping power of the fingers should not be interfered with. Drop wrist can be easily and safely corrected at the end of about ten days, without disturbing the broken fragments of the radius. Early and frequent inspection and application of heat and light massage are most helpful. The type of anesthetic used to accomplish reduction is a matter of election. I prefer a general anesthetic.

DR. WILLIS C. CAMPBELL, Memphis, Tenn. I have reviewed forty five cases of elderly persons with Colles' fracture. This is a terminal fracture and all terminal fractures are delayed to some extent particularly in old persons. In all fractures of the neck and femur, and even of the external condyle of the humerus in children, nonunion occurs if they are not in perfect apposition. I think that the fluoroscope is a dangerous method and I speak from personal experience. Many of my confreres have suffered afterward. However roentgenography should be employed in all cases of Colles' fracture during the course of the operation. This can be accomplished by roentgenograms, rapidly developed, and the same results can be obtained. I

have not seen any great amount of delay of union in these cases, if reduction was accomplished. I believe that the reason shortening occurs in some of these cases is absorption of the rather atrophic bone afterward. In some of the cases, regardless of what is done, some shortening of the wrist will occur. The flexed position should not be maintained over a long period of time in elderly patients. I apply plaster-of-paris splints next to the skin and have been able to immobilize the fracture quite satisfactorily after reduction. The bad results are due to the fact that Colles' fractures are not given subsequent roentgen study. Roentgenograms should be made at the end of one week. If the fracture is in good position at that time, it will be maintained. I have had a number of fractures that showed some tilting at the end of the week, at which time they could be easily corrected. If this is carried out, the end result will be good. At the end of three weeks another roentgenogram should confirm the position. In elderly persons I remove the posterior portion of the splint and give massage with no motion for six weeks, except in the fingers. In young persons it makes no difference whether or not the splint is removed, because the complications of edema and swelling that occur in adults are lacking and excellent results may be obtained in practically all young persons. The results Dr. Haggart has shown are excellent. I believe that results are not as good in elderly persons as in the young. I know that I have seen some cases of my own at a later time when there has been some shortening of the radius, but on the whole the results are good. Strong traction should be made on the thumb. The reduction is made in the usual manner, but, if strong traction is made on the thumb, many of these radii can be elongated to their normal position and the anatomic landmarks restored.

DR. ROBERT H. KENNEDY, New York. Patients with Colles' fractures are treated by orthopedic surgeons, general surgeons and general practitioners throughout the country. The results are nothing to boast of, whichever group carries out the treatment. The results are comparable to the amount of interest the doctor has in this particular lesion. The public has not learned that many fractures can be treated in such a way that permanent deformity and permanent functional loss are not necessary. Many doctors have the same defeatist attitude. There is no excuse for ever attempting to reduce any Colles' fracture without an anesthetic, unless facilities for it absolutely cannot be obtained within twelve hours. This is not a question of the possibility of obtaining reduction or the ability of the patient to stand pain, but of assurance that no further damage to tissue will be caused by the reduction. I have found the use of local anesthesia quite satisfactory in elderly patients. Too commonly it is stated that at the person's advanced age the result will be good enough without any reduction. A doctor who gives this advice is not granting his patient the advantage of present-day knowledge of treatment. Anything short of a 10 to 15 degree anterior facing of the lower articular surface of the radius means permanent disability and anything short of complete reduction of the dislocation of the inferior radio-ulnar articulation means constant pain on rotation. I do not mean that these replacements can always be obtained, but I do mean that it is inexcusable not to try. I am frequently surprised to find how simple the reduction is in a case I am tempted to sidestep. Even when the patient is seen a week after the fracture occurred, one should not be satisfied without attempting reduction under complete anesthesia. Either doctors must learn to read their roentgenograms or they must insist that roentgenologists give more detailed reports in the instance of Colles' fractures. A typewritten report of "satisfactory reduction" means nothing. I believe that the only satisfactory reduction is 100 per cent perfect, but, as I said many surgeons believe that no attempt at reduction is satisfactory. Roentgenologists can be as variable in their interpretation of the word satisfactory. I have been given this report many times when analysis of the roentgenogram shows a position that will result in permanent disability and constant pain. The doctor giving treatment should analyze his own roentgenograms, but, if he does not do this, he should employ a roentgenologist who reports on fractures in mathematical terms of angles, axes and apposition. Roentgenologists should not be expected to have as much knowledge of fractures and as much interest in them as physicians. I cannot agree with the general use of the fluoroscope

while reducing Colles' fractures. It entails too much danger to the surgeon who does it frequently.

DR. ROLAND HAMMOND, Providence, R. I. In treating comminuted Colles' fracture in elderly patients, there are two deformities to overcome. First, one must restore the radial styloid to its proper position, and the ulnar styloid must be brought up. In my experience, unless those fractures are held in absolute position for from a week to ten days, one will have a gradual molding back into deformity. For that reason I have found the sugar tong splint unsatisfactory. I apply a circular plaster bandage from above the elbow to the knuckle joints, but I do more than simply flex the wrist or bring it into ulnar deviation, I put a little twist into it so that the ulnar styloid comes up. That absolutely maintains the radial styloid in position and reduces most of the deformity. The cast should not be left on for more than a week or ten days. At that time it is surprising what amount of firmness has been obtained in the fracture and one may then go to wooden removable splints with the assurance that the fracture will remain in position. The difficulty is reading the roentgenograms afterward with the wrist in this twisted position, but one soon learns to do it.

DR. G. E. HAGGART, Boston. What Drs. Kennedy and Campbell have said is correct. I didn't mean to imply that I reduced them under the fluoroscope all the time. The point they bring out is that the quick-snap roentgenograms will even do away with that. My point is that one should have vision of the fracture immediately following reduction at the time one puts the splint on and then check it with the plate. I feel that in the comminuted type of fracture in elderly patients, if one can prevent pronation and supination, it will help in maintaining the position one secures. The principle of no reduction is decidedly pernicious and any one should have the opportunity of treatment. As to Dr. Hammond's remarks, I am a little unhappy about softened plaster. In this type of splint, one can control it and adjust it to fit the degree of circulatory change much more satisfactorily than with the other splint.

Clinical Notes, Suggestions and New Instruments

SPONTANEOUS INTRAPERITONEAL RUPTURE OF THE NORMAL URINARY BLADDER

ROGER W. BARNES, M.D., and A. A. STEELE, M.D.
LOS ANGELES

Rupture of the urinary bladder without trauma and without a predisposing pathologic condition is sufficiently rare to justify the report of a case.

L. F., a man, Spanish, aged 34, entered the hospital the evening of Aug. 3, 1935. About eighteen hours before, while straining to void, he had a sudden severe pain in the lower part of the abdomen, which caused him to faint. He had been playing cards for four hours and had not voided during that time. A high-ball was taken before dinner, otherwise there had been no ingestion of liquor. This was corroborated by others present at the time, as was also his statement of having had no injury. Previous to this his health was excellent, and he had never had any genito-urinary symptoms.

A physician was called, and because of the complete absence of any previous or present genito-urinary symptoms the patient was kept under observation and treated palliatively. Fifteen hours later he felt the desire to void and passed only a small amount of blood. He was immediately sent to the hospital.

The patient was well developed and well nourished. He complained of extreme pain in the lower part of the abdomen. This was found to be rigid and somewhat tender. Three hundred and fifty cubic centimeters of bloody urine was obtained by catheterization. Otherwise the examination was essentially negative.

A roentgenogram of the urinary tract showed a shadow in the region of the lower end of the right ureter, very suggestive

of a calculus. A tentative diagnosis of ureteral calculus was made, and cystoscopic examination advised.

A No. 24 cystoscope was passed very easily and the bladder was found to contain numerous large blood clots. When these were evacuated through the cystoscope, the bleeding point was visualized in the dome of the bladder. Closer inspection revealed a ragged tear in the bladder mucosa at this point, and a diagnosis of intraperitoneal rupture of the bladder was made. The bladder was otherwise entirely normal. There was no evidence of obstruction at the bladder neck, no ulceration of the mucosa and no trabeculation. A No. 9 bougie met no obstruction when passed 30 cm. up the right ureter. A cystogram showed the characteristic ill defined outline of the fundus of the bladder, and diffusion of the cystographic fluid through out the lower part of the abdomen confirmed the diagnosis.

A laparotomy was done immediately, and when the peritoneum was opened a large amount of bloody fluid was found free in the peritoneal cavity. When this was aspirated, a ragged opening into which three fingers could be inserted was found extending from the peritoneal cavity to the bladder, situated just to the right of the midline in the posterosuperior portion of the bladder. No other intraperitoneal injury or abnormality was found. The tear was sutured in two layers with No. 2, forty-day chromic catgut, a stab wound was made through the abdominal wall on the right side, two rubber tissue drains were inserted to the site of the rupture, and the peritoneum was closed. The bladder was then opened extraperitoneally. Its interior was examined and found to be normal except for the tear that had just been sutured. A suprapubic catheter was fastened into place by a purse-string suture, and the abdominal incision was closed.

Following the operation the patient had considerable abdominal distention from intestinal gas, which was fairly well controlled by the Levine tube and gas enemas. Otherwise his convalescence was uneventful, the suprapubic catheter being removed on the ninth postoperative day and a urethral catheter inserted. The suprapubic opening healed rapidly and remained closed after the urethral catheter was removed on the thirteenth postoperative day. He left the hospital in good condition on the fifteenth postoperative day.

Stone,¹ in 1931, reported two cases of so-called spontaneous rupture of the bladder, gave an excellent review of the literature, and summarized the cases reported before that time. He found forty-two cases, in twenty-one of which there was no lesion in the bladder. The probable cause of rupture in these twenty-one cases was as follows: manual expression of placenta, one, during labor, five, attempted micturition during acute retention (cause of retention not given), six, intoxication without trauma (?), three, straining at stool, three, sudden lifting of weight, three.

Since 1931 there have been three cases² of so-called spontaneous rupture of the bladder reported: one in a woman with chronic retention and overflow (no cause of retention found), one a tuberculous bladder, and one a subacute retention due to gonococcal urethritis. In each of these, pathologic changes in the bladder or urethra preceded the rupture.

In the case reported there had been no previous genito-urinary symptoms. There was no pathologic condition in the bladder in the urethra or at the bladder neck, and previous ingestion of liquor had not been sufficient to cause intoxication. No history of trauma could be obtained. It is probable that the distended bladder produced sufficient edema about the bladder neck to cause some obstruction and, when the patient strained to void, the intravesical pressure was sufficient to cause the rupture. This case makes a total of twenty-two cases of spontaneous rupture of a normal bladder that have been reported. Even though it is rare, the condition should be considered in any case presenting the symptom of sudden severe pain in the lower part of the abdomen.

COMPLICATIONS FOLLOWING USE OF SACCHARIN
AND ETHER AS A CIRCULATION TIME TEST

HARRY D LEINOFF M.D NEW YORK

In 1933 soluble saccharin (sodium orthosulphumbenzoate) was introduced by Fishberg and his associates¹ as a means for measuring the circulation time. A year later Hitzig² introduced ether to measure the efficiency of the right heart. The combination of these two methods has been popularly designated as the saccharin ether test for circulation time. In both of these communications the authors stress the safety and lack of both local and systemic reactions. It is my purpose to report two serious accidents following the use of this test.

TECHNIC

Saccharin Method Three grams of soluble saccharin is placed in a dry tube and autoclaved for ten minutes, then 3 cc of sterile triple distilled water is added and the mixture is gently heated until the solution is completed. This is allowed to cool and 25 cc is injected intravenously through a number 19 gage needle as rapidly as feasible. The time necessary for the saccharin to travel from the site of injection to the tongue is measured. This is called the arm to tongue time and is normally from eight to sixteen seconds.

Ether Method Two and five-tenths cubic centimeters of a 10 per cent ether in saline solution is injected intravenously and the time interval between the moment of injection and the appearance of ether on the patient's breath is measured.

REPORT OF CASES

CASE 1—L B, a white woman, aged 31, was admitted, April 13, 1935, with a diagnosis of acute catarrhal jaundice. Three days later circulation time studies were done. The arm to lung (ether test) was 68 seconds unfortunately the patient moved her arm during the saccharin test and some of the solution infiltrated the perivascular tissue. She immediately complained of a very sharp pain and the injection was stopped. The antecubital space showed an infiltration and a dark bluish discoloration. The arm was treated with hot moist dressings and improved clinically in a few days. Though the patient still complained of some pain in her arm she was discharged, April 24. At this time the involved area was tender and covered with a very dark, dry bluish scab. At no time did the patient have any fever. A few days later the infiltrated area became very painful and swollen, with red streaks extending up into the arm and down into the forearm associated with an axillary lymphadenitis. The temperature ranged from 101 to 103.5 F. The involved area was incised and drained a gelatinous material for ten days. Complete healing took place in about four weeks.

CASE 2—F G a white man, aged 32 was admitted April 17, 1935, with a diagnosis of bronchial asthma. The patient was discharged twelve days later with no improvement in the condition. May 9, on readmission he complained of a severe asthmatic attack of three days duration, during which time he had been unable to obtain any relief. The examination of the patient showed a typical asthmatic chest, a right frontal sinusitis and an eosinophilia of 23 per cent. May 15 it was decided to do circulation-time studies in order to rule out a possible cardiac origin for the asthma as suggested by Blumgart.³ Immediately preceding the tests the patient was examined. The lungs revealed typical signs of asthma, the heart sounds were distant, the blood pressure was 100 systolic, 82 diastolic and the pulse rate 84. The saccharin solution was injected giving a time of sixteen seconds which corresponded to the upper limits of normal. The ether solution was now injected, and immediately the patient began to cough and experience great difficulty in breathing. He became markedly cyanotic, the chest was fixed in expiration and the pulse rate became extremely rapid and thready. The chest revealed barely audible heart sounds and the respiratory murmur was inaudible with occa-

sional dry rales. In spite of all emergency therapy used at the time, such as epinephrine intravenously and intracardially, the patient died. A postmortem examination was not obtained. The ether time in this case was normal.

COMMENT

Because of the simplicity of the test and the ease with which it can be done by every one, I think that a word of warning should be sounded in reference to the possible complications.

In the first case there can be no doubt that the perivascular infiltration of saccharin produced an atypical inflammation that lasted five weeks. The character of the discharge was distinctly different from the usual collection of pus suggesting a chemical type of irritation. It is possible that the jaundice in this case contributed toward the atypical reaction of the tissues. However in some of the other cases in which infiltration of saccharin took place no deleterious effects were noted.

In discussing the second case very little can be said from a dogmatic point of view. The cause and effect were too closely related to each other to leave any doubt about the part that the test played in the production of this patient's death. I do not think that the test in itself caused the patient's death, but certainly it was the precipitating factor in an already extremely hypersensitive individual. Immediately after this incident the entire batch of materials that had been used was injected into a cat in the physiology laboratory to determine whether any toxic results could be obtained. No abnormal effects resulted.

VISCERA RETAINER

R W McNEALY M.D CHICAGO

The experience of many surgeons teaches that it is often more difficult to close the abdomen of an obese or muscular patient than it is to perform the preceding steps of the operation. If the patient takes a poor anesthesia and is inclined to strain or breathe irregularly, the difficulties of closure will be increased.

Many ingenious instruments have been devised to help retain the viscera beneath the level of the edges of the peritoneum

A steel reinforced soft rubber viscera retainer

during the course of parietal closure. If such instruments are to be wide enough to offer any material aid they are usually awkward to remove when the peritoneum is closed very far. If lap pads are used to retain the omentum and intestine, their extraction is often accomplished with considerable tugging, and the intestine or omental tags are pulled through the opening.

The instrument that I have devised and used for some time has the general shape of a sole fish. It is made of soft Para rubber of about 3 mm thickness and has a central reinforce-

ment of flat steel of about 1.5 mm thickness, which runs from one end to within 5 cm of the other. This piece of steel is 2 cm wide and has an eye in the forward end through which braided silk is passed.

The central stay reinforcement usually is passed beyond each end of the peritoneal opening and the soft rubber sides spread out beneath the peritoneum to prevent the omentum and intestine from escaping. The braided silk cord with a ring attached protrudes through the lower end of the wound. This retainer can be left in the abdomen until the opening is sutured to within 3 cm of its end, when the braided silk can be used to slip the eye of the retainer into the wound. The soft rubber sides will fold on the central steel reinforcement and permit of easy removal. The moist rubber surfaces will not drag on intestine or omentum. The advantages of the instrument may be summarized as follows:

- 1 It is easily sterilized
 - 2 It can be inserted readily and easily removed
 - 3 It does not scrape the peritoneal surfaces
 - 4 It efficiently retains omentum and viscera during the difficult periods in the closure of the peritoneum

RECENT ADVANCES IN ENDOCRINOLOGY

RELATION TO INTERPRETATION AND UNDER-
STANDING OF COMMON SYMPTOMS

CLINICAL LECTURE AT ATLANTIC CITY
SESSION

DAVID PRESWICK BARR, M.D.
ST. LOUIS

It requires no wide acquaintance with endocrinology to realize that the practical application of organotherapy has lagged far behind advances in anatomic and physiologic knowledge. Although medication with thyroid and insulin and even with epinephrine and solution of posterior pituitary has been conspicuously successful, the clinical use of more recently discovered substances, such as parathyroid extract, adrenal cortex extract, estrogenic substance and anterior pituitary-like principle from the urine of pregnancy, is restricted and sometimes disappointing. Many preparations, such as the active principle of the corpus luteum, the testicular hormones and the growth, thyrotropic and adrenotropic fractions of the hypophysis, while capable of causing predictable effects in experimental animals, have had for one reason or another limited application in the treatment of disease. If specific therapy were the sole aim of the study of glands of internal secretion, there might be some reason for discouragement on the part of practitioners. It is apparent, however, that the significance of endocrinologic research cannot be measured by this criterion alone and that it must be judged also by the light which investigation has shed on the understanding of disease in general. With increasing knowledge of the hormones, many common symptoms and maladies have acquired new interest. Ideas concerning pathogenesis have been transformed and previously unrecognized interrelationships have been revealed. It is with this aspect of the recent developments in endocrinology that I am concerned here.

From the Department of Medicine, Washington University School of Medicine and the Barnes Hospital.

Read before the General Scientific Meeting at the Eighty-Sixth Annual Session of the American Medical Association, Atlantic City, N. J., June 11, 1935.

Needless to say, a thorough survey will not be possible. Already the glands of internal secretion are known to affect the most diverse clinical conditions. Adiposity, hypertrichosis, abnormal pigmentation, hypertension, menstrual disorders, disturbances in carbohydrate metabolism, decalcification of the skeleton and polycythemia are only a few of the pathologic states in which endocrine influences can be demonstrated. From this vast array of possible subjects I have chosen to consider only three and shall limit my discussion to the influence which newer knowledge of the glands of internal secretion has had on the concepts of hypertension, obesity and disturbances in carbohydrate metabolism. The reasons for selecting these particular conditions are, first, that they are extremely common disorders and form a part of the experience of every practitioner, second, they are to some extent interrelated and, lastly, much attention has been given of late to the possibility of their surgical or roentgenologic treatment.

HYPERTENSION

Experience has taught that hypertension must be regarded as a symptom rather than as a disease. The lability and variability of the blood pressure, apparent under physiologic states of exertion and emotion, are more evident in association with pathologic states. It accompanies such different conditions as increased intracranial pressure, thyrotoxicosis, eclampsia and glomerular nephritis. In so-called malignant hypertension the association with arteriolar sclerosis is so early as to suggest the possibility that the high blood pressure is actually caused by primary disease of the blood vessels. While these and other factors are known to contribute to elevated pressure, hypertension is most often encountered in the condition that has been called hyperpiesis, or essential hypertension, a form in which the etiology is almost entirely unknown and in which early correlated anatomic lesions cannot be demonstrated. The realization that essential hypertension tends to be familial and to a certain extent hereditary does not explain its mechanism, and it is in this type of high blood pressure that the hope of demonstrating some relatively simple endocrine factors has long been entertained.

When epinephrine, the pressor substance of the adrenal medulla, was discovered it was immediately supposed, and quite naturally, that clinical disturbances in the level of blood pressure might be explained by its excessive or defective secretion or by an abnormal response of the hypertensive individual to its physiologic effect. The idea was strengthened by the claim, not well substantiated, that the adrenal medulla is hypertrophied in hypertension,¹ and by the disclosure that epinephrine produces hyperglycemia and glycosuria,² signs not infrequently encountered in association with clinical hypertension.³ In spite of this theoretical probability, efforts to prove that the usual case of high blood pressure is dependent on abnormal relations to epinephrine have in general been disappointing.

The detection of the pressor substance in the blood stream offers great difficulties because of its extreme dilution. In the adrenal vein it has been found in

amounts corresponding to not more than one part in 360,000, which indicates that in the general circulation it might reach dilutions of 1 100,000,000,⁴ an amount so small that present chemical tests are not applicable, and even the extremely delicate physiologic methods are insufficient for quantitative estimations. Under such circumstances reliable comparisons between normal and pathologic individuals are not to be expected, and actual efforts to demonstrate increased amounts of epinephrine in the circulating blood of hypertensive subjects have led to conflicting results.⁵ Similarly, efforts to show that patients with high blood pressure are unduly sensitive to epinephrine have been unsuccessful, and there is at present no convincing evidence that the vascular system of such subjects responds abnormally to the pressor substance from the adrenal.⁶

It should be added that many physiologists have been opposed to the view that epinephrine is responsible for the maintenance of normal blood pressure or for the production of continued elevation. Cannon⁷ indeed believes that there is no sustained discharge of epinephrine but that it is a part of a supplementary mechanism which becomes active only in emergency.

In spite of such adverse opinion the possibility that excessive amounts of epinephrine produced in the body may cause temporary or even permanent high blood pressure has been established through study of paragangliomas, tumors derived from the chromaffin system and from those cells known to be active in the usual elaboration of epinephrine. In a number of instances such tumors have been accompanied by paroxysmal attacks of excessively high blood pressure.⁸ Sudden elevation of systolic pressure from normal to 300 or more with corresponding changes in diastolic have been observed and have been accompanied by colicky pain, anginoid attacks, mydriasis, dyspnea, pallor, glycosuria and hyperglycemia, symptoms which may be seen following the therapeutic injection of epinephrine in sensitive individuals. Analyses have shown that the tumors contain variable and at times extremely large amounts of epinephrine. Kalk,⁹ using both chemical and physiologic methods, found from 375 to 500 mg of the substance in the tumor on which he reported. When it is remembered that the amount of epinephrine which Schmorl¹⁰ found in two normal adrenals was only 4.22 mg, and when it is recalled how small an intravenous dose of epinephrine is necessary to produce a rise in blood pressure, the enormity of such values is readily appreciated. In one case Ernould and Picard¹¹ believed that they could demonstrate an increased amount of epinephrine in the circulating blood.

While in the early stages of paragangliomas the symptoms and the elevation in blood pressure are paroxysmal, continuance of the cause may result in permanent hypertension, and autopsy may reveal in the kidneys, retinal vessels and elsewhere changes that are scarcely distinguishable from those of essential hypertension.¹² As is well known, removal of a paraganglioma in the earlier stage of its development may result in establishment of completely normal blood pressure and permanent cure.¹²

Study of these chromaffin tumors does not necessarily lead to the inference that cases of essential hypertension are due to excessive epinephrine. It does demonstrate that a picture clinically and pathologically quite similar may be produced by an excess of epinephrine arising in the chromaffin system of the affected individual.

Paragangliomas are not the only tumors of the adrenals in which elevated blood pressure has been observed. It has also been seen with cortical tumors and with hyperplasia of cortical cells.¹³ Clinically many of these tumors have been accompanied by hirsutism, amenorrhea, obesity and other symptoms now recognized as typical of the adrenocortical syndrome. Although in one such case Langeron, Paget and Loheac¹⁴ found a great increase in the epinephrine content of the tumor tissue, in another only a trace was present. In spite of the fact that lesions have not often been of such a nature as to indicate direct involvement of the medulla, the blood pressure has been consistently elevated. In its character, however, it differs from hypertension associated with paraganglioma. Ordinarily the elevation is not extreme, the systolic pressure varying from 140 to 180, the diastolic from 95 to 120. There are no paroxysmal attacks, and diurnal variations in the blood pressure, while present, are not striking. In several cases the removal of tumors has been accompanied by a fall in blood pressure to normal levels.¹⁵

The association of high blood pressure with adrenal cortical tumors is of special interest in connection with the recent observation of Cushing¹⁶ on the functions of the basophil cells of the hypophysis. As is now well known, the relatively rare adenomas of the basophil cells of the pituitary have been in a surprising number of instances associated with a syndrome which is almost, if not quite, indistinguishable from that which has been ascribed to adrenal cortical tumors. In addition to the hirsutism, obesity, menstrual disturbances and other features, hypertension of about the same level and character is an almost constant feature.

Cushing has laid great emphasis on reasons for considering that the basophil cells may be in some degree responsible for the hypertension.¹⁷ The logical steps in such reasoning may be outlined. Solution of posterior pituitary, the substance extractable from the posterior lobe, is capable of producing elevation in blood pressure

somewhat less dramatic but considerably more prolonged than that following epinephrine. Although this substance is stored in the posterior lobe and can be extracted from it, there is much reason for the belief that it is not formed in the cells of the nervous tissue constituting the substance of the posterior portion of the hypophysis. It seems more likely that it is a secretion of the cells of the pars intermedia which are basophilic in their staining reaction and are distinguishable with difficulty from the basophil cells of the anterior lobe and from those found in basophilic adenoma. Such cells are not always confined to the pars intermedia but may wander out into the posterior lobe, where they are seen as collections of cells still receptive to the basic dyes. Cushing emphasized the increased invasion of the posterior lobe by such cells in hypertensive and in eclamptic individuals and has suggested that both the proliferation of cells and the invasion of the posterior lobe may be significant in the etiology of elevated blood pressure. This fascinating hypothesis has stimulated much thought and work but is still open to question. Study of a larger number of hypophyses by many observers has led to the impression that the number of basophilic cells increases with the age of the individual, that they are greater in number in hypersthenic than in asthenic individuals, thus in general tending to show predilection for the type of patient statistically most likely to have high blood pressure, and that they tend to accumulate to a greater extent in the posterior lobe in hypertensive individuals.¹⁸ It has also become evident, however, that such cells may not be demonstrable in some cases with excessively high pressure and may on the contrary be seen in young individuals whose blood pressure has been normal.¹⁹

The trend of recent work has supported the contention that anatomic lesions of both the adrenals and the pituitary may be coincident with and possibly responsible for considerable changes in blood pressure and that the associated lesions are not limited to the medulla of the adrenal, the supposed source of epinephrine, or to the posterior hypophysis, where the active substance, solution of posterior pituitary, is stored, but that they may also occur in the adrenal cortex and in the basophil cells of the anterior hypophysis. While it by no means follows that ordinary cases of hypertension are dependent on similar changes, the possibility of adrenal and hypophyseal participation is established.

OBESITY

Less perhaps can be said of the effect of recent endocrine developments on our understanding of obesity. Clinical and laboratory experience has demonstrated that although such factors as lack of exercise and excessive consumption of food are of great importance in the production of adiposity, they are not sufficient to permit great fat accumulation in all individuals. That excessive obesity is familial and to a certain extent hereditary does not explain the mechanism of fat deposition. For many years there has been an effort to attribute excessive obesity, whether familial or otherwise, to endocrine dysfunction. Classification has usually been attempted on the basis of the distribution of fat, which varies widely in obese subjects. Emphasis

has been placed on the occurrence of excessive trochanteric fat as an expression of hypogonadism, and of fat accumulation in the supraclavicular regions and about the wrists and ankles as evidence of lowered thyroid function. Subcutaneous deposits about the hips, thighs, the mons and the lower part of the abdomen, the so-called girdle obesity, has been considered as evidence of pituitary insufficiency.²⁰ Although interest in these classifications has not lessened, it is now recognized that some of the conclusions were in part premature. Even the conception of hypophyseal obesity has undergone considerable change. The basis for attributing girdle obesity to pituitary insufficiency arose from the study of Froehlich's syndrome. Froehlich's original case was attributed to a pituitary tumor,²¹ and apparent confirmation of such an association was obtained from many reports of similar symptoms developing in patients who suffered from pituitary lesions. As other cases of the adipose genital syndrome accumulated, however, it became evident that the same clinical picture could arise with extrasellar tumors and that it was not unusual to see cases in which the hypophysis was entirely uninvolved.²² More commonly lesions are found in the region of the hypothalamus, and, even in those cases in which the hypophysis is primarily affected, pressure or invasion of the hypothalamus is excluded with difficulty.

In experiments with rats, Philip Smith²³ was able to show that complete removal of the hypophysis without injury to the adjoining nervous tissue caused no adiposity. On the other hand, chemical damage to the hypothalamus with no injury to the hypophysis resulted in marked accumulation of fat. While these beautiful observations of Smith are usually considered decisive in disproving the primary importance of the pituitary gland in the causation of the Froehlich type of obesity, they have not discouraged the effort to associate the distribution of fat with endocrine disorders.

Cushing's study of the clinical symptoms accompanying basophil tumors of the hypophysis has emphasized the so-called buffalo type of obesity, a distribution characterized by accumulation of fat on the face, neck and trunk, with relative slenderness of both arms and legs. It is often accompanied by the appearance of large red striae on the abdomen and on the upper portion of the thighs and is not infrequently painful.¹⁸ It has also been seen in typical form in the presence of adrenocortical tumors.¹³

While this curious and characteristic distribution of fat is perhaps the most convincing evidence of endocrine influence thus far available, it is not yet clear whether the picture is to be ascribed primarily to pituitary or to adrenal influence. The recent experiments of Thompson and Cushing²⁴ are of great interest. Because of the supposed relationship between the basophil cells and the sex stimulating hormones of the hypophysis, they conceived the idea that the long continued injection of active gonadotropic hormones into young animals might produce some of the symp-

toms observed with basophilic tumors. The injected animals were retarded in skeletal development and became both adipose and plethoric.

DISTURBANCES IN CARBOHYDRATE METABOLISM

With the discovery of insulin and the demonstration of the rôle played by the islands of Langerhans in its production, the view previously held that diabetes is dependent on disease of the pancreas was apparently confirmed. The nature of diabetes could be redefined as a condition dependent on disease involving the islands of Langerhans and on the deprivation of insulin.²⁵

Although this view has been widely accepted, it does not explain with entire satisfaction some clinical and experimental observations. Pathologic studies of the pancreas in ordinary diabetes have failed to demonstrate constant lesions. In his study of the pancreas in nondiabetic patients, Warren²⁶ showed that practically any lesion found in the pancreas of diabetic patients could be duplicated in nondiabetic patients and concluded that it was impossible to diagnose the presence or absence of diabetes from a study of the pancreas. Even in cases in which death has resulted from the severity of the diabetes the islands of Langerhans may deviate but little from the normal, and it would appear that the anatomic mechanism for the production of insulin is well preserved.

Another difficulty has arisen from the study of insulin resistance and insulin sensitivity. Even in the early days of the use of insulin cases were encountered in which unusually large doses were required. Time has added a great number, and it is now recognized that in the presence of infection, in some cases of hyperthyroidism,²⁷ in hemochromatosis,²⁸ in hepatic disorders and in the presence of some forms of pituitary disease²⁹ the effectiveness of a given dose of insulin may be greatly decreased.³⁰ Such insulin resistant cases have also been encountered in the absence of these obvious factors. Other cases have shown an abnormal sensitiveness to insulin in that slight excess of the dosage required to control the diabetic condition produces hypoglycemia and its accompanying symptoms. It has been shown that the amount of insulin necessary to cause a fall in blood sugar varies widely both in diabetic and in nondiabetic patients. Doses of 0.001 unit per kilogram have been sufficient in some cases, while in others as much as 0.5 unit per kilogram was necessary.³¹ Such observations clearly indicate that there is no definite or constant relationship between the amount of insulin and the amount of carbohydrate which it will cause to be utilized. They suggest that there might be some contraregulatory mechanism capable of neutralizing the effect of insulin.

Recent work has thrown much light on this possibility and has indicated that both the pituitary and the

adrenals are concerned with the activity of insulin and with the severity or mildness of diabetes.

Glycosuria is a symptom in about 25 per cent of the cases of acromegaly.³² One half of the cases of basophilic tumors of the hypophysis have exhibited diabetes. On the other hand, certain cases of lowered pituitary function, such as Simmonds' disease, have shown a high tolerance for carbohydrate and at the same time an extraordinary sensitiveness to insulin.³³

The experiments of Houssay,³⁴ which were repeated by Barnes and others,³⁵ have been of crucial importance. It was found that hypophysectomy in animals from which the pancreas had been completely removed lessened the degree of glycosuria and hyperglycemia and at the same time induced a state of sensitiveness to insulin so great that the administration of one unit might be sufficient to produce hypoglycemic convulsions. In Barnes's dog no spontaneous glycosuria appeared during many weeks of observation, a high sugar tolerance being the only evidence of the loss of pancreas and of the diabetic state. On the other hand, injections of extracts of pituitary, containing the so-called diabetogenic principle produced glycosuria. In Long's depancreatized and hypophysectomized cats, such extracts were capable of causing excessive glycosuria, hyperglycemia, ketosis, coma and death.

A conclusion drawn from such experiments has been that the pituitary contains a principle which lessens the effectiveness of insulin and that the absence of this principle following hypophysectomy renders the animal sensitive even to very small amounts of the pancreatic substance.

Still more informing are the recent experiments of Long³⁶ and his collaborators. After overcoming enormous technical difficulties they are now able to prepare cats from which both the pancreas and the two adrenals have been removed. With minor variations the effect is the same as in the Houssay dogs. There is marked lessening of the severity of the diabetes and, if an active suprarenal cortical extract is given, a great prolongation of life. One important difference has been noted between Houssay's dogs and Long's cats. The adrenalectomized and depancreatized animal does not respond even to large doses of a pituitary extract that causes fatal ketosis in the hypophysectomized and pancreatectomized animals.

The natural conclusion to draw from these experiments is that action of the anterior pituitary substance is possible only through the mediation of the adrenals. Removal either of the pituitary or of the adrenal glands will lessen the severity of the diabetes and produce sensitiveness to insulin. The protection against pancreatectomy is removed by injection of solution of pituitary when the adrenals are present but is not altered when they have been removed.

One surprising outcome of Long's work is that adrenal cortex extract, the active principle of the

adrenal cortex, while capable of prolonging the life of the adrenalectomized animals and of protecting them from the usual concomitants of adrenal insufficiency, will not confer on them the power of reacting to the pituitary principle

One other result of Long's important experiment should be noted. It is well recognized that epinephrine, the product of adrenal development, acts as an antagonist to insulin. Simultaneous injections of epinephrine and insulin show opposite effects on the level of blood sugar. It would therefore be a reasonable inference that the increased sensitivity to insulin and other effects which are seen to follow adrenalectomy might be attributed to the absence or diminution of epinephrine. Long's experiments indicate that this is not the correct explanation. Animals from which one entire adrenal and the medulla of the other have been removed are not protected against pancreatectomy or the hyperglycemia and ketosis that follow. Apparently this is strong evidence that the cortex of the adrenal is an active factor in carbohydrate metabolism.³⁷

From such observations it is clear that disease of the pancreas is not the only influence in the clinical conditions of diabetes and hyperinsulinism. Experimental evidence indicates a possible mechanism by which clinical cases of insulin sensitivity and resistance might be explained. It appears that a state closely simulating clinical diabetes or the opposite condition of hyperinsulinism might arise from factors other than disease of the pancreas and might be attributed either to abnormal resistance or to abnormal sensitivity to the product of the pancreatic islets.

THE OCCURRENCE OF ANATOMIC AND FUNCTIONAL DISEASE

All the conditions that have been discussed may accompany and, under some circumstances, seem to be at least in part dependent on organic disease of the pituitary or of the adrenals. Hypertension may be a feature of pituitary basophil tumors, of cortical tumors of the adrenal and in its paroxysmal form of paragangliomas of the medulla. The buffalo type of obesity is encountered with both basophil and adrenal tumors. Diabetes and even more often hyperglycemia and demonstrable disturbances in carbohydrate storage are accompaniments both of acromegaly and of Cushing's disease and have also been reported with adrenocortical tumors. Hypoglycemia has been seen in association with destruction of the hypophysis, and insulin sensitiveness characterizes pituitary cachexia and hypophysectomy. That these common conditions may be associated with anatomic endocrine disease has thus been conclusively demonstrated. The fact remains, however, that the great majority of cases of hypertension, obesity, diabetes and hypoglycemia display no clinical evidence either of pituitary or of adrenal disease. It might be claimed, therefore, that although the exceptional case may be ascribable to endocrine factors, the usual picture has nothing to do with them. Before accepting such a contention as final it is important to consider some of the factors involved. Clinically the means of recognizing pituitary and adrenal disease are extremely crude. Roentgen examinations of the skull, study of the visual fields, the search for neighborhood symptoms, and roentgenograms of the upper part of the abdomen are feeble diagnostic methods for

determining even gross anatomic defects. More and more evidence is accumulating that for overfunctioning of a gland of internal secretion a tumor is not necessary. In the thyroid,³⁸ parathyroid³⁹ and pancreas⁴⁰ it has been repeatedly demonstrated that hyperplasia not always grossly perceptible may produce symptoms referable to oversecretion. Already this is apparent in the studies that have been made in regard to the adrenal and is suspected from studies of the pituitary. Furthermore, it must be remembered that the condition of no gland is static and that some and presumably all are constantly adapting themselves to changing conditions of internal and external environment. Recent studies of the thyroid gland have shown how labile it is from an anatomic standpoint and how easily it is affected by a great number of different circumstances.³⁹ One of the best examples of anatomic and physiologic adaptation is encountered in the study of interrelations between the hypophysis and the ovaries. At puberty, during the menstrual cycles, during pregnancy and lactation, and at the menopause these organs are undergoing constant changes which are morphologically recognizable and which have been established more recently by functional and hormone studies.⁴¹ In these relationships, moreover, temporary imbalance is demonstrable and not infrequent. Disturbances in the amount or in the timing of anatomic and functional changes may lead to clinical disease such as the anovulatory type of menstruation, to amenorrhea, to the complicated symptomatology of the menopause, or to delayed lactation. The time is past, therefore, when the participation of glands of internal secretion in pictures of disease can be judged solely by demonstrable anatomic changes. The possibility cannot be denied that the pituitary, the adrenals and perhaps other glands as well are involved not only in the rare case presenting a demonstrable tumor but in all cases of essential hypertension, upper body obesity and diabetes.

The clinical recognition of pituitary basophilism or of the adrenocortical syndrome does not depend on any single manifestation but on a combination of symptoms: hypertrichosis, amenorrhea, obesity of the upper body type, high blood pressure, disturbances in carbohydrate metabolism, sometimes decalcification of the skeleton and polycythemia. With our present experience such an association of symptoms in advanced form would appear to be unmistakable evidence of adrenal or of pituitary disease or of both. Such an assumption has in many instances led to the demonstration of a tumor or of significant hyperplasia and in some cases has resulted in surgical removal and dramatic cure. The symptoms themselves are among those most frequently encountered in clinical medicine. Moreover, they are often seen together in the same individual. Common associations are hirsutism, particularly of the face and chin, in plethoric obese women, obesity accompanied by long periods of amenorrhea, the diabetes of bearded women, obesity with hypertension, obesity accompanied

by a prediabetic state or by frank diabetes, and finally obesity with both hypertension and hyperglycemia

With the consideration of such pictures of disease, the practical aspect of the subject under discussion in this paper becomes apparent. There seems to be no sharp dividing line between the obvious adrenal and pituitary syndromes and those which reveal combinations of two or more of the characteristic symptoms. For any physician who has permitted himself to become fully aware of the recent advances in pituitary and adrenal physiology, the temptation is great to consider all these conditions in the same category and to adopt for the mild cases the same therapeutic approach that has proved successful in the more advanced.

The importance of establishing criteria by which a separation can be made is indicated by the emphasis recently given to various surgical and radiologic procedures suggested for the treatment of these conditions. Irradiation of the pituitary region has been suggested not only for the control of pituitary basophilism⁴⁰ but also for hypertension⁴². Subtotal adrenalectomy has been advocated in the treatment of hypertension⁴³. Denervation of the adrenals,⁴⁴ section of splanchnic nerves and section of the anterior roots of spinal nerves,⁴⁵ although based on somewhat different conceptions, have as part of their rationale the hope of controlling excessive adrenal activity.

The fundamental soundness of considering ordinary cases of hypertension, obesity and diabetes as possibly related to disturbed pituitary and adrenal function should not blind one to the fact that this is as yet only a hypothesis dependent for its validity in large part on analogy and circumstantial evidence. It must not be forgotten that the present surgical and roentgenologic approach in therapy is experimental and accompanied by no small dangers. To proceed wisely in such a situation requires sound knowledge of existing facts, caution and conservatism in the clinical application of laboratory evidence and perhaps, above all, a mind open and prepared for the advances that will doubtless be made in the next few years.

SUMMARY

Advances in the study of glands of internal secretion cannot be judged solely or chiefly by the extent to which they lead to successful organotherapy but more by the profound influence they have on the understanding and interpretation of common symptoms. Consideration of their relation to hypertension, obesity and disturbances in carbohydrate metabolism is of especial importance because of the frequency of such manifestations, because they are often encountered in the same individual and because in certain striking instances they are directly attributable to pathologic changes in the hypophysis or the adrenals. Although participation of these and other glands of internal secretion must be suspected in many cases of high blood pressure, obesity and diabetes, caution is necessary lest the newer knowledge be applied prematurely and too extensively in surgical and radiologic treatment.

NONSPECIFIC PROTEINS

A NUMBER OF FIRMS ARE ADVERTISING NONSPECIFIC PROTEIN PREPARATIONS UNDER PROPRIETARY AND SOMETIMES MEANINGLESS NAMES. RELATIVELY FEW OF THESE PREPARATIONS HAVE BEEN SUBMITTED TO THE COUNCIL ON PHARMACY AND CHEMISTRY AND NO PROPRIETARY NON-SPECIFIC PROTEIN PREPARATION HAS BEEN ACCEPTED FOR INCLUSION IN NEW AND NONOFFICIAL REMEDIES. BELIEVING THAT PHYSICIANS DESIRE A MORE EXTENSIVE PRESENTATION OF INFORMATION CONCERNING NON-SPECIFIC PROTEIN PREPARATIONS THE COUNCIL ON PHARMACY AND CHEMISTRY HAS AUTHORIZED PUBLICATION OF THE FOLLOWING REVIEW. IN ADOPTING THIS REPORT THE COUNCIL EXPRESSES APPRECIATION TO THE AUTHORS OF THESE ARTICLES: DR. RUSSELL L. CECIL AND LUDVIG HEKTOEN.

PAUL NICHOLAS LEECH, Secretary

THE REACTIONS TO THE NONSPECIFIC PROTEIN TREATMENT OF INFECTIOUS DISEASES

LUDVIG HEKTOEN, M.D.
CHICAGO

The writings about the effects of nonspecific protein treatment, therapeutic and otherwise, have been reviewed by others¹ and are considered in the article by Cecil, which follows. Hence this literature will not be considered in detail here. As used in this article the term nonspecific protein refers to proteins of different antigenic and other properties than the microbes concerned in the diseases subjected to the treatment.

The usual obvious effects of the intravenous injection of foreign proteins of any kind are chill, fever, headache, and gastro-intestinal and other disturbances. These effects are dependent on and associated with humoral and cellular changes of complex nature. In its typical form the protein reaction reaches its height a few hours after the injection, and in infectious states the subsidence of the reaction may be followed by clinical improvement. The benefit seems to bear some relation to the general reaction and fever, the higher the fever, the better may be the results. Depending on the kind and on the quantity of protein injected as well as on the patient and his disease, the effects of such injections are subject to much variation. Whether there are any true qualitative differences in the reactions under different conditions has not been determined. The acute protein reaction resembles the immediate reactive response to acute infection in which foreign proteins enter the body in the form of infectious microbes.

Can the acute protein reaction and its results be explained by the operations of some single, central mechanism? At present the nearest we can come to any explanation seems to be to assume that as the foreign proteins mix with the fluids of the body and are taken up by cells, especially in the reticulo-endothelial system, humoral and intracellular processes result, the products of which affect the entire organism in a characteristic but complex fashion. The ensuing phenomena are partly evanescent, partly more or less permanent. Weichardt has advanced the view that these phenomena are the expression of a general stimulation of cellular activities. Certain phases of the protein reaction may be considered briefly.

A prompt but evanescent effect is exercised on the autonomic or sympathetic nervous system. In the

splanchnic area vascular dilatation associated with secretory stimulations develops at the same time as peripheral vessels are contracted, hence the chill. Before long this action on the vessels is reversed and then comes the reestablishment of the normal state. The substance or substances that cause these vascular phenomena have not been determined. The fever indicates a simultaneous increase in chemical activities. At first there develops a peripheral leukopenia, which is succeeded by leukocytosis as the acute reaction subsides. Whether the leukocytes now have a greater phagocytic power than normally does not seem to have been determined, but generally leukocytosis is regarded as an anti-infectious reaction. Of other changes in the blood may be mentioned increase in proteolytic and lipolytic enzymes, diminution and then increase in fibrinogen and complement, lessening in the colloidal stability of the plasma, and increase in nonprotein nitrogen.

The capillary walls and the reticulo-endothelial system are believed to be the sites of important processes in nonspecific treatment. A temporary increase in phagocytic activity and in permeability is assumed. Local edema results and substances accumulate that may destroy bacteria and toxic substances. It is probable that the products of the breakdown of free and ingested foreign proteins and other substances may have marked local and general effects. Substances with vasodilator actions, such as histamine and choline, as well as products with other effects may be liberated from the tissues. Histamine causes vascular reactions like those that result from injury to tissues. The focal reactions in nonspecific protein treatment may depend more or less on such processes.

Intravenous injection of foreign proteins may give rise to acute reactions in existing inflammatory areas, especially those of infectious origin. Such reactions may develop in localizations of the particular infection under treatment as well as in other processes even when unsuspected and latent. These focal reactions indicate that inflammatory tissues are sensitive to the effects of the protein injection. The vessels may be more or less dilated beforehand, reticulo-endothelial and other cells may be abnormally active and even specifically sensitive or allergic. The conditions for rapid diffusions and consequent interactions are favorable. These focal reactions may be interpreted as the outcome of nonspecific and of specific (allergic) processes. The local result may be healing with or without disintegration of tissue. In acute reactions in infectious foci, antigenic substances may be liberated to stimulate the production of antibodies and other specific anti-infectious processes. Rarely the flare-ups may result in untoward complications of protein treatment. Hench² has described an instructive series of cases of this nature, including such conditions as appendicitis, cholecystitis, iritis and pericarditis.

Whether the normal antibodies and other microbicidal substances in the blood are increased in nonspecific protein treatment has not been determined. From the results of experiments on animals it has been inferred that in infectious conditions nonspecific proteins may stimulate renewed formation of specific antibodies, but here again no positive statements are warranted because adequate observations on patients in the course of treatment do not seem to have been made.

This statement is true even of typhoid, which has yielded the most striking results of the acute infectious

diseases subjected to intravenous protein injections, specific as well as nonspecific. It is said that one third of patients with typhoid so treated recover by crisis, that one third are improved, and that in one third the treatment is without apparent curative effect. No complete explanation can be offered for these differences in results. As the main localizations of typhoid are in the splanchnic lymphatic apparatus, they are involved directly in the reactions following the protein injection, but whether the curative effects are caused by the sudden stimulation of specific antityphoidal processes, by increase in enzyme actions, by the activities of new leukocytes or by combinations of these processes are questions one cannot answer. Detailed observations are needed on patients under different forms of protein treatment. It has not been determined whether the treatment of typhoid with nonspecific proteins gives the same results as treatment with specific proteins, that is, vaccines of typhoid bacilli or of closely related bacteria. Neither has it been determined whether there is more production of specific antibodies on the injection of specific than on the injection of nonspecific proteins in typhoid.

The nonspecific proteins—serum, milk, vaccines—used in treatment are in themselves antigenic and may call forth homologous or specific antibodies, which however would not be expected to exercise any therapeutic effect as such under the conditions in hand. But, as stated before, the injection of new antigen may stimulate renewed production of antibodies against the antigen or antigens of previous immunizations. This is the so-called anamnestic reaction—the previous process is recalled into action. This phenomenon shows that immunization has a lasting effect on the organism. It seems as if antigen enters and remains in the cells in which antibodies are synthesized. Probably the first to point this out were Salmonsens and Madsen³ in their studies of the reproduction of diphtheria antitoxin after large losses of blood. They said that this reproduction results from the acquirement by certain cells of a new and lasting secretory power under the influence of the toxin. It should be remembered then that the therapeutic use of protein may give rise to more or less permanent sensitizations, that the effects of antigenic proteins are more permanent than the effects of pharmacologic agents, and that the body can produce many different antibodies—carry many different sensitizations—at the same time.

There is no evidence that nonantigenic substances can initiate *de novo* the production of antibodies, but in animal experiments it has been found that certain nonantigenic substances (e.g., pilocarpine, metallic salts) may increase the concentration of antibodies in the blood in the early stages of formation as well as induce secondary rises after the apex of the antibody curve in the blood has been passed. It is perhaps doubtful whether these effects are due to stimulation of production or to mobilization of existing antibodies. In the acute protein reaction, substances may arise which can act like pilocarpine in animal immunization.

In view of all the possibilities referred to in the foregoing, it seems fully warranted to interpret the effects of nonspecific proteins in infectious diseases as the results of the activation of nonspecific as well as specific anti-infectious processes. Much further study, especially of the changes in the human body, is needed.

to give a clearer insight into the intimate nature of these processes as they occur under various conditions. There can be no doubt that the scope and nature of the reactions to injected proteins in infectious states depend in large measure on the circumstance that the tissues of the patients have been stimulated and sensitized by infectious and antigenic substances. So far but little advantage has been taken of the opportunities to make careful and detailed studies on patients in the course of treatment. To understand better the reactions to different nonspecific proteins in infections, analysis is needed also of the effects caused by such proteins in apparent good general health. And comprehensive observations are indicated on animal diseases that correspond as much as possible to the human diseases subjected to nonspecific protein treatment.

Therapeutics

THE THERAPEUTICS OF THE COOK COUNTY HOSPITAL

EDITED BY BERNARD FANTUS, M.D.
CHICAGO

NOTE.—In their elaboration these articles are submitted to the members of the attending staff of the Cook County Hospital by the director of therapeutics Dr. Bernard Fantus. The views expressed by various members are incorporated in the final draft for publication. The articles will be continued from time to time in these columns. When completed, the series will be published in book form.—Ed

THE THERAPY OF INJURIES TO LARGE BLOOD VESSELS

IN COLLABORATION WITH DR. RAYMOND
W. MCNEALY

In injuries involving the large vessels, dramatic onset and rapid development of the clinical climax which places the patient's life or limb in jeopardy demands immediate, decisive and correct treatment. The indications are hemostasis, care of complicating injuries, maintenance of life, maintenance of distal circulation and appropriate after-care.

HEMOSTASIS

Temporary Hemostasis—(a) **Constriction of Limb Above the Wound (Esmarch Bandage)**. When a wound is bleeding in jets, pressure should be applied above, not to the wound itself. Immediate help should be rendered in these emergencies, at the scene of the accident, by some one who at once with both hands grasps and squeezes the entire circumference of the limb while some one else ties any available thick cord or other fabric around the limb, slips any available rod under the knot, and by means of the rod twists the knot until the bleeding is checked. When any foreign body of considerable size has been driven into a wound, this body should be left in place as its forcible removal may start a fatal hemorrhage. Indeed, the rule should be given the public "Do not touch the wound." A general knowledge of these two principles might save many a life.

The surgeon performs essentially the same service by compressing the principal artery of the limb above the wound at the point of election and then applying a

tourniquet. Esmarch long ago emphasized certain principles in the application of tourniquets which should be kept in mind. 1 Elevation of the extremity before application assists in hemostasis. 2 The tourniquet should never be applied to the lower part of the leg or to the forearm, because the blood vessels escape compression between the two bones of the part. 3 The tourniquet should be applied to the adductor side first, to secure immediate arterial occlusion without marked venous congestion. 4 Caution must be exercised to prevent sudden flexion or extension of the limb after the viselike constricting tourniquet has been applied. 5 The tourniquet should not be applied in successive overlying loops, because each loop then exaggerates the constriction of the preceding one. An interval should be allowed between the loops. 6 The tourniquet should not be left on any longer than is absolutely necessary.

The most common error in putting on a tourniquet is applying it with force less than that of the systolic blood pressure. This permits serious congestion distally and aggravates the bleeding. A frequent cause for this error is that the tourniquet is applied while the patient is in shock and when only a light constriction suffices to stop the bleeding. In the first reaction after shock the systolic pressure rises above that of the constricting tourniquet, which then becomes actually detrimental in the control of hemorrhage. Some reservation must be made in both the force and the duration of application of the tourniquet in individuals with diseased arteries. Inordinate pressure may rupture the intima of sclerotic arteries and result in local thrombosis. Prolonged constriction of these vessels may also lead to distal thrombosis, with similar disastrous consequences to the limb.

(b) Direct Aseptic Compression (Tamponade)

This is an additional recourse available to the surgeon, which becomes especially important in locations that do not admit of the application of a tourniquet, such as the neck, the trunk and the immediate roots of the limbs.

A series of ingenious methods of arterial control has been developed. In each location, surgeons have taken full advantage of local anatomic conditions to devise easier and more reliable methods of controlling hemorrhage. These include such maneuvers as the intercostal plug in intercostal hemorrhage, pneumothorax in wounds of the pulmonary vessels, the rectal tampon and the spring and elastic compressors. Full advantage is also taken of all direct compressions, especially those which utilize adjacent bony prominences against which the compression can be made, and of the assistance which simple elevation renders.

Concealed hemorrhage, in the absence of profuse external hemorrhage, may be of sufficient severity even to endanger life. The gravity of hemothorax or hemoperitoneum is apparent, but the dangers attending interstitial hemorrhages are not sufficiently appreciated. Large quantities of blood plasma may be lost from the physiologic circuit into the loose tissues of the groin or the axilla, without blood leaving the body. A serious isolation of formed elements from the blood stream occurs in interstitial hemorrhages accompanying injuries to large vessels. The fluid elements are quickly absorbed leaving more space for packing and concentration of formed elements. An interstitial hematoma of 1 liter may actually represent a blood loss of 2 liters. These situations demand intervention with almost as much urgency as does profuse external

hemorrhage These local interstitial losses of blood can usually be stopped by direct compression or by tourniquet application, if the site is suitable, in exactly the same manner as is profuse external hemorrhage

In many cases the external hemorrhage is quickly and easily controlled or the hemorrhage, if concealed, checked in extent before there is any primary dangerous loss of blood These cases must not be dropped from careful observation, because in some the improvement of circulatory activity precipitates recurrent hemorrhage or extension of the hematoma, which eventually, though insidiously, is as dangerous to life and limb as was the initial acute profuse hemorrhage The extrusion of consecutive clots from an open wound or the intermittent progressive extension (not migration) of a hematoma demands immediate intervention before serious secondary accidents develop These signs mean that one of the larger arteries has been injured, and for such injury there is only one remedy direct stopping of the leak by either suture or ligation of the bleeding vessel In such cases one should rarely rely on tamponade or the hope that a clot will be formed sufficiently firm to stop the hemorrhage

At the bedside of every patient liable to secondary hemorrhage from an injured limb there should hang a rubber tube to be used by the nurse as a tourniquet the moment such hemorrhage is discovered and even before the doctor is notified

In locations where proximal constriction is impossible, direct pressure to the bleeding vessel should be applied by the nurse either by means of a sterile dressing or, in extreme emergency, even by grasping and tightly squeezing the wound with hand or, this failing, by plugging the hole in the vessel wall with the bare fingers until the doctor can be summoned

The latter may rapidly insert a hemostat or stuff the largest possible tampon into the wound, temporarily closing it with a few deep sutures so as to permit adequate preparation for operation and the induction of anesthesia

Permanent Hemostasis—This demands, first of all, asepsis When life is at stake, when it seems that the patient is bleeding to death before one's eyes, the immediate stopping of the hemorrhage takes precedence over all other considerations The moment the vital necessity has been taken care of, there should be no further precipitate action Now all the requirements of surgical asepsis must be fully met, for infection makes permanent hemostasis illusory, the sloughing of perivascular and vascular tissue leading to repeated and disastrous secondary hemorrhages

If it is decided that the vessel involved is small and unimportant and that operative intervention may not be necessary, the wound is loosely sutured and kept under close watch until all danger of hemorrhage or of spreading infection has passed If it should be felt, however, that an important vessel is involved, there should be no temporizing with packing or continued direct compression, even though the wound is small and apparently clean These measures only prevent the free drainage from the wound of foreign and occultly infected material They expose the patient to the possibility of repeated secondary hemorrhages by exaggerating and complementing what may originally have been only a minimal contamination In such cases the vessel should be first controlled by provisional occlusion and then exposed freely, the original accidental wound being avoided as far as possible The

final restorative or obliterative management of the vessel wound is then accomplished according to the indications discussed later

In doubtful cases, when the size of the vessel is not known but there are minimal soft tissue injuries and there is no gross contamination or infection, the wound is left unsutured and carefully watched At the first evidence of recurrent bleeding, clot extrusion or developing infection, surgical intervention is demanded If the indication for intervention is recurrent external bleeding or extending hematoma or progressive clot extrusion, the surgical approach may be made as in the preceding type of case If the indication is infection only, the situation is met by simple adequate drainage of the infected region

The most harrowing situations in blood vessel surgery are those in which infection is accompanied by secondary hemorrhage In these cases the problem of stopping further secondary hemorrhage is even more important than that of preventing gangrene Too often temporizing measures are hazarded to preserve circulation in the limb at the cost of the patient's life by hemorrhage from failure to secure decisive control of the vessel The majority of mistakes in handling such problems occur when an attempt is made to ligate the bleeding vessel by approach through the original infected wound

For permanent hemostasis it is necessary to choose between (a) ligation at a distance, (b) direct ligation and (c) blood vessel repair

(a) Ligation at a distance should be undertaken in all cases of secondary hemorrhage with infection and in all cases with extensive injuries to the soft parts or with evident gross contamination, for in these a moderate or even severe infection can usually be anticipated Such cases should therefore be handled just as if they were already infected and recurrently bleeding In deep, profusely bleeding wounds, much time and often much blood is lost in attempts to find and ligate the bleeding vessel In such cases the wound would have to be much enlarged, as it is difficult to recognize the landmarks in an area infiltrated with blood It may be the better plan therefore to expose the main trunk higher up and ligate it in continuity

While the technic of the classic ligation of the various large blood vessels cannot be discussed here in detail, certain general principles may be emphasized It is highly desirable to secure a diminution of the intraluminal pressure against which the ligation has otherwise to be tightened by temporary proximal compression of the vessel while the ligation is being drawn into place This reduces the force and crushing that is otherwise necessary to bring the vessel walls into apposition A double thread of coarse silk is then passed under the artery and the first thread is tightened slowly and steadily and knotted Then, just above and close to it, the second thread is placed in the same manner

(b) Direct ligation of the bleeding vessel becomes necessary when conditions prevent proximal ligation, as, for example, at the immediate root of an extremity or the base of the neck or where the collateral circulation is so rich as to allow continued hemorrhage, as in the hand, foot, head or neck It should also be undertaken even after ligation at a distance has been accomplished, in order to avoid secondary hemorrhage

The original wound should now be opened up freely, cleansed, and the ends of the divided vessels caught up and tied above as well as below the point of injury

When oozing of blood from a deep wound is so profuse that it may be impossible to recognize the structures at the bottom, one may, to save blood, plug the cavity firmly with sterile gauze and then, as soon as the bleeding has been controlled, gradually raise the tampon, a small portion at a time, applying forceps to each bleeding point as it is exposed.

Neither forceps pressure nor ligation should ever be applied to tissue *en masse*, but only directly to the bleeding vessels, so as not to injure accompanying veins or nerves.

When there is infection in situations in which ligation at a distance is impossible, an incision is made over the bleeding vessel, the original wound being avoided as far as possible, and, with a minimum of dissection, the vessel is exposed and controlled. Its division is completed if necessary and the ends are closed by nonabsorbable suture. The incision is left freely open. The infected area is then freely incised to provide adequate drainage, and great care is exercised to expose every ramification of the spread of the infection. The importance under these conditions of completing the division of the vessel, as well as the importance of minimizing the dissection and the use of nonabsorbable ligature, must be emphasized.

While it is true that, as a general proposition, only absorbable suture material should be used in the presence of infection, in vascular surgery the presence of infection is the one condition that demands the use of nonabsorbable suture material, as only on it can sufficient reliance be placed. Infection prevents or delays the occlusive sealing of vessel walls. Occlusive thrombi are readily liquefied and there is urgent necessity for prolonged artificial occlusion by the ligature. Catgut with its uncertain absorbability cannot be relied on in these situations. Silk or linen must be used. This suggestion is not antagonistic to the doctrine that infected fields do not tolerate nonabsorbable suture material. This teaching applies only to situations in which the nonabsorbable material is buried within the wound. The condition which answers the objection to the use of silk or linen as ligature or suture material in infected vessel wounds is that these wounds be left widely open, just as Pare's amputation wounds were left widely open. For small vessels, fine silk ligature will serve. For larger vessels it is better policy to use thick ligature material, because this insures broad apposition with less devitalizing compression. Abernethy says "When an artery is tied with a thick ligature, the compression made by it is not so great as to produce a speedy mortification and separation of the end of the vessel so that the ligature remains in general a fortnight before it is detached and therefore time is allowed for the consolidation of the sides of the vessel prior to the separation." Simple ligature is often adequate. However, the advantage of ligature by transfixion is, in general, obvious.

Either ligature or transfixion is applicable only when a material segment of the artery is exposed and sufficiently free from adjacent important structures. When the dissection necessary to obtain this vessel exposure would invite extension of the infection or jeopardize adjacent structures, another of the later developments of vessel technic should be utilized—closure of the divided vessel ends by suture. This suture carefully avoids all perivascular structures.

The proper management of the accompanying undamaged veins is still in question. Previous to 1913 it was a rather well founded idea that in wounds of

large arteries the concomitant ligation of the accompanying vein led to gangrene of that extremity more frequently than did ligation of the artery alone. In 1913 the attention of the British surgeon Makins was called to the fact that, in the treatment of arteriovenous aneurysms, fewer cases of gangrene developed when the vein also was ligated than when only the artery was occluded. The studies of Oppel, Wieting, Holman and Edwards, and Brooks and Martin confirmed the observation that simultaneous vein ligation would be of considerable value in reducing the frequency of gangrene when the artery had been or had to be obliterated. This conclusion has been almost universally accepted, although the mechanism whereby gangrene is diminished is still in dispute. Wilson summarizes the theories propounded as follows:

1 Ligation of the vein restores the "balance of the circulation." This implies a belief that in occlusion of the artery alone the capacious main vein affords a too ready outlet for the diminished quantity of blood reaching the part below the occlusion. The blood tends to supply mainly the proximal tissues of this part and is not dispersed to the distal tissues. There is thus a condition of unbalance between inflow and outflow which, it is claimed, can be corrected by venous occlusion. A closely allied idea is that venous ligation keeps the blood in longer contact with the tissues, which are presumably enabled thus to extract more oxygen from it.

2 The theory has been formulated by Brooks of a more homogeneous distribution of the arterial blood. The main favorable influence according to him is the raised intravascular pressure, which serves to keep the capillaries patent in areas in which they would otherwise collapse, and this distributes the arterial blood more uniformly throughout the tissues.

3 The theory of the development of a "richer collateral bed" is the conclusion from certain injection experiments.

4 The theory of "masked sympathectomy" has been advanced by Leriche and Fontaine. They believe that the initial rise of arterial pressure in the limb after venous ligation is associated with a transient peripheral vasoconstriction, which is succeeded in some minutes by active vasodilatation and that these effects are produced by reflex action along sympathetic nerve fibers.

The results of Wilson's own experimental studies are not in accord with the previous experimental work on the subject. They do not support the current belief that ligation of the main vein diminishes the incidence of gangrene which follows ligation of the main artery. His results may possibly lead back to the older views, which encouraged preservation of the concomitant vein. These conflicting views from reliable sources make it inadvisable to take an arbitrary stand in this question until more evidence has been accumulated.

(c) With regard to blood vessel repair, in unimportant vessels or when collateral circulation is abundant it is better not to indulge in reparative methods. A simple obliterative method should then be used. At any point, in the presence of infection or of diseased vessel tissue, reparative suture should not be used. Thrombosis practically always follows and vitiates the purpose of the reparative surgery. The added manipulation required for the reparative suture only serves to aggravate the infection. It is much safer under these circumstances to resort at once, even with major vessels, to obliterative control, although one knowingly faces the possibility of subsequent gangrene.

In case of a small wound or perforation of the major vessel and when asepsis is possible, reparative suture is the method of choice. This is particularly the case in those locations in which gangrene is more likely to occur than in others. Thus, gangrene is much more likely to occur after main trunk injuries of the lower extremity and is rare after comparable injuries in the upper extremity. The most vulnerable sites of all are above the profunda branch of the femoral artery, in the popliteal region, and above the profunda branch of the brachial artery. In these locations especially are reparative methods desirable.

In cases in which the penetrating or incised wound is sharply cut and circumscribed, with no evident gross contamination, and especially when the wound edges have been freely washed by the outflow of blood, the danger of infection is usually slight. Restorative sutures are put in with the simplest possible technic and the least amount of manipulation, after the lumen of the artery has been temporarily occluded above and below the injury. If the wound in the vessel is uneven, its edges are freshened before suture. In small lateral wounds the continuous cross suture of fine silk is applied with closely set stitches, perforation of the intima being avoided as far as possible. The external coat is then brought together by a second continuous suture in an endeavor to secure a blood-tight closure without undue encroachment on the caliber of the vessel.

If the lateral wound exceeds two thirds of the circumference of the vessel, the accepted policy is to complete the division of the vessel, to freshen the ends and to perform an end-to-end anastomosis. If the resection required exceeds three-fourths inch, in most situations it will be impossible to effect a direct anastomosis without excessive tension. This can be obviated only by the insertion of a vein transplant or by using a Tuffier¹ tube. These may carry the main blood flow for a sufficient period of time to allow the adequate development of collaterals, but these are very hazardous procedures.

CARE OF COMPLICATING INJURIES

In wounds of large blood vessels, surgical management should be concentrated primarily on the care of the blood vessel wound. The care of concomitant injuries to tendons, nerves and bones should usually be relegated as much as they safely can be to a later period. When the management of the blood vessel wound requires obliteration of its lumen, the acute deficiency in blood supply makes the success of primary nerve or tendon suture dubious. When the blood vessel lumen is restored or reconstructed by suture, further extensive manipulation in the vicinity, in an effort to resuture the soft tissues accurately, jeopardizes the vessel repair on which the success of the whole operation primarily depends.

Such wounds should be sutured but loosely if at all. A common error is the accurate suture of the overlying tissues in ignorance of the vessel wound and the sealing in of foreign material, blood coagulum and whatever bacteria were included, to play secondary havoc with the vessel. The procedure to be followed in these cases depends on the size and importance of the vessel implicated. An estimate of the importance of the vessel injured may be obtained from the amount and force of the hemorrhage sustained before the temporary artificial control was applied. The points of entrance and

exit and the probable path of a missile are also of some value, but they may be very misleading because of the erratic course which missiles often take between muscle and fascial planes.

Drains are rarely indicated in the management of vessel wounds. If suture or ligation has been done in a clean wound, drains not only withdraw the plastic exudate necessary for rapid healing but invite infection from the surface. If the wound is infected or contaminated, it should be left widely open. In these cases, drainage with closure is a compromise measure which ensnares only those who have not seen the disastrous consequences of this procedure. In case of doubt, it is much better to leave the wound widely open.

MAINTENANCE OF LIFE

Under conditions ideal for the management of these desperate cases, one should almost always include preoperative blood transfusion. This condition, however, is not frequently fulfilled. Compatible donors are often not immediately available. In cases in which a tourniquet has been applied to an extremity, the delay attending the selection of a donor and the administration of blood, coupled with the time necessarily consumed in the definitive operation, may exceed the period during which the limb can safely tolerate a deprivation of circulating blood. In locations where hemostasis is effected by direct compression rather than by application of a tourniquet, more time may be available for selection of a donor and blood transfusion. In every instance, if blood transfusion is not available, intravenous injection of physiologic solution of sodium chloride or acacia solution should be administered before or during the operation. In addition, in the desperate cases, full advantage should be taken of the effect of autotransfusion by bandaging the limbs.

A prophylactic dose of tetanus antitoxin (1,500 units) should not be omitted.

MAINTENANCE OF DISTAL CIRCULATION

The fourth factor for consideration in vessel wounds is the actual or potential damage to the circulation distal to the point of injury. The actual damage is that directly sustained through the trauma. The potential damage is measured by two factors. First is that which may be added by an increasing hematoma which shuts off the collateral supply. Second is that which is determined by the surgical sacrifice of vessel lumen incidental to the operative intervention. The viability of the part supplied by the injured vessel depends on the summation of these three factors. To estimate them one must know the importance of the vessel trunk injured to the life of the part it supplied, the abundance of the collateral circulation present to take its place, the extent of the direct damage to the vessel, the amount of hematoma pressure and the limits of effective surgical intervention imposed by destruction of tissue and concomitant infection or disease.

The preoperative status of the circulation distal to the point of injury can sometimes be determined by careful palpation or by the Pachon oscillometer. In the presence of alarming hemorrhage, however, this determination must wait on the control of the bleeding. In the extremities it can then be determined only during the first part of the operation, when provisional control has been substituted for the tourniquet. The provisional control is cautiously released and the amount of impairment of distal circulation is ascertained. From this apparent impairment must be sub-

¹ Klotz, O., Permar, H. H. and Guthrie, C. C. End Results of Arterial Transplants. *Ann. Surg.* 78: 305 (Sept.) 1923.

tracted the factor of arterial spasm, which may be present in greater or lesser degree after vessel injuries or temporary constriction of the afferent circulation.

The final result of the management of acute vessel injuries requires not only the control of hemorrhage and of infection and the reduction to a practical minimum of the amount of vascular loss but the maintenance also of the life of the part supplied by the vessel involved. In many cases the amount of vessel substance that is lost or must be sacrificed to save the patient from fatal hemorrhage or infection is more than the limb can spare. Survival of the part is then secured only by the rapid and abundant development of collateral channels. Successful results were obtained in blood vessel surgery long before the importance of this collateral circulation was recognized. Even today in many cases in which some intricate method of vessel wound management is instituted, success is obtained not by virtue of the ingenuity of the surgical procedure but by the incidental generous development of collateral vascular channels.

The most recent major contribution to blood vessel surgery is the recognition of the importance of the collateral flow, and the discovery of methods that stimulate collateral blood vessel development to its greatest possible maximum. All adjuvants to the development of collaterals such as postural exercises, intermittent application of heat, passive vascular exercise by positive and negative pressures, intermittent venous congestion, or vasoconstrictor paralysis by nerve block are recommended as elective features of the postoperative program. Active encouragement in the use of these methods will reduce the percentage of postoperative gangrene and improve results to some extent.

POSTOPERATIVE CARE

While much depends on a nice choice of operative procedure in the care of the vessel wound and adjacent parts, too often the advantages thereby gained are promptly lost by injudicious postoperative care. In clean cases the details of postoperative care are designed to maintain the part in a physiologic norm. Both extremes of management, varying from unrestricted activity to the rigid immobilization and encasement that were so popular a generation ago, are to be avoided.

The part is kept in a comfortable position and a small amount of activity is encouraged. In the extremities this activity should be confined to the small acral muscles. It should not include gross movements of flexion and extension which puts a dangerous strain on suture lines and invites the loosening of emboli. The maximum benefits are gained when movements are not pushed to the point of fatigue. The part is protected from decubital pressure, especially over the bony prominences. It is kept warm, but extreme caution is exercised to avoid burning or maceration. The deficient blood supply lowers the resistance of the tissues to thermic insults.

In the infected cases, dependent and adequate drainage must be maintained. Full advantage is taken of the position in which the part is placed to maintain dependent drainage. Warm, moist dressings are used sparingly because the heat is difficult to stabilize, the moisture leads to maceration, and the dressing as a whole serves to obstruct free drainage. Frequent irrigation or treatment with dilute solution of sodium hypochlorite is much more advisable.

Council on Pharmacy and Chemistry

NEW AND NONOFFICIAL REMEDIES

THE FOLLOWING ADDITIONAL ARTICLES HAVE BEEN ACCEPTED AS CONFORMING TO THE RULES OF THE COUNCIL ON PHARMACY AND CHEMISTRY OF THE AMERICAN MEDICAL ASSOCIATION FOR ADMISSION TO NEW AND NONOFFICIAL REMEDIES. A COPY OF THE RULES ON WHICH THE COUNCIL BASES ITS ACTION WILL BE SENT ON APPLICATION.

Allergic Extracts-Mulford are prepared by extracting various substances with buffered salt solution consisting of monobasic potassium phosphate (KH_2PO_4) 0.363 Gm, dibasic sodium phosphate (Na_2HPO_4) 1.43 Gm and sodium chloride (NaCl) 5 Gm in 1 liter of distilled water containing 0.4 per cent of phenol.

Products marked 1 are prepared for extraction as follows. The crude material is ground as fine as possible. The powder or flour, is placed in a Buchner funnel and washed with carbon tetrachloride until the washings are clear and colorless. The carbon tetrachloride is removed with ether. The washings are discarded and the residue is dried. The dried residue is extracted under toluene with buffered salt solution from one to three days at room temperature.

Products marked 2 are prepared for extraction as follows. The fruits or vegetables are ground as fine as possible. Buffered salt solution is added to the ground pulp and allowed to extract under toluene from one to three days at room temperature.

Products marked 3 are prepared for extraction as follows. The muscle fibers after the removal of fat and tendons are ground as fine as possible. The ground muscle is washed with toluene until free from fats and oils. The toluene washings are discarded. The ground meat is extracted under toluene with buffered salt solution from one to three days at room temperature.

Products marked 4 are prepared for extraction as follows. The feathers or hair are washed with ether and the suspended particles of dander are collected by filtration. The dried material is extracted under toluene with buffered salt solution from one to three days at room temperature.

Preparations marked 5 are prepared for extraction as follows. The yolk of an egg is separated from the white in a sterile manner. One part of egg white, or egg yolk, is diluted with four parts of sterile buffered salt solution.

Lactalbumen marked 6 is prepared for extraction as follows. The fat from 1 liter of milk is removed by centrifugation. The fat free milk is saturated at 30 C with magnesium sulphate which precipitates the caseinogen and lactoglobulin. The filtrate is acidified with acetic acid so that the content of the acid is 1 per cent. The precipitate is filtered off pressed out and dissolved in water, the solution is neutralized and dialyzed (Practical Organic and Bio Chemistry R H A Plummer p 446).

Milk, marked 7 is prepared for extraction as follows. One liter of fresh nonheated milk from which the fat has been removed by centrifugation is mixed with 3 cc of 1 per cent rennin solution and placed in a water bath at 37 C for one-half hour. The precipitated casein is removed by straining through a sterile towel. The filtrate is neutralized with saturated solution of sodium bicarbonate and sterilized by filtration (J Immunol 15:2 1928).

Dust, marked 8 is prepared for extraction as follows. The dust is washed with ether and extracted under toluene with a mixture of two parts of alkaline extracting fluid (2.5 Gm of sodium bicarbonate and 5 Gm of sodium chloride in 1 liter of distilled water) and one part of buffered salt solution saturated with carbon dioxide. The extract is dialyzed against the same fluid passing carbon dioxide constantly during the period of dialysis. After dialysis, the extract is evaporated (electric fan) and during the process carbon dioxide is kept constantly bubbling through the fluid (J Immunol 15:2 1928).

Horse serum marked 9 is prepared for extraction as follows. Normal horse serum containing 0.4 per cent of phenol as a preservative is used. Glue marked 10 is prepared for extraction as follows. Glue is extracted with buffered salt solution.

Allergic Extracts Mulford are tested and standardized in terms of protein units. The unit is fixed at 0.001 mg of protein. The total nitrogen is determined by the Kjeldahl method. The total nitrogen in milligrams multiplied by 6.25 equals total protein in milligrams. The total protein in milligrams divided by 0.001 equals the total number of protein units.

ACRIFLAVINE BASE (See New and Nonofficial Remedies, 1935, p 185)

Acriflavine Neutral-Calco—A brand of acriflavine base—N N R

Tablets Acriflavine Neutral-Calco $\frac{1}{2}$ grain (uncoated)

SCARLET RED MEDICINAL BIEBRICH (See New and Nonofficial Remedies, 1935, p 180)

Scarlet Red Medicinal Biebrich-Calco—A brand of scarlet red medicinal Biebrich—N N R

IPRAL SODIUM (See THE JOURNAL, June 1, 1935, p 1999)

The following dosage forms have been accepted

Ipral Sodium Tablets $\frac{3}{4}$ grain
Ipral Sodium Tablets 2 grains

ANAEROBIC ANTITOXIN (See New and Nonofficial Remedies, 1935, p 366)

Parke, Davis & Co., Detroit.

Gas-Gangrene Antitoxin (Combined) Refined and Concentrated P D & Co—Also marketed in vials containing 10 000 units of perfringens antitoxin and 10 000 units of vibrio septique antitoxin

Committee on Foods

THE COMMITTEE HAS AUTHORIZED PUBLICATION OF THE FOLLOWING REPORTS
RAYMOND HERTWIG Secretary

NOT ACCEPTABLE

GUNZENHAUSER CREAM-NUT BREAD

The Gunzenhauser Bakery, Inc., of Lancaster, Pa., submitted to the Committee on Foods a white bread named Cream Nut Bread and prepared from white flour, water, condensed skim milk, lard, sodium chloride, sucrose, yeast, powdered skim milk, malt extract and a yeast food containing calcium sulphate, ammonium chloride, sodium chloride and potassium bromate.

Discussion of Name—The name "Cream-Nut" implies the presence of cream and nuts in substantial quantities in the baking formula and sufficient to give the bread qualities and nutritional values not possessed. Cream and nuts are not ingredients and skim milk is the only milk product constituent. The name therefore is inappropriate and misleading. Food names should truthfully describe foods.

The bakery was advised over a year ago of the Committee's criticisms but as yet has not demonstrated that a change has been made in the product name. This bread, therefore, will not be listed among the Committee's accepted foods.

NOT ACCEPTABLE

ELTOLA DIETETIC LEGUME FLOUR

Manufacturer—Eltola Flour Company, Huntington, W Va.

Description—Powdered legume (Lupinus) flour

Manufacture—Lupinus seeds, a legume product from Palestine, Syria and other tropical countries are cleaned of foreign materials, washed with water, soaked in a solution of sodium bicarbonate and sodium chloride to remove the bitter taste, removed from the solution, spread on tables to dry, ground, sifted to remove the coarse hull material, and packed in wax paper bags in cartons.

Analysis (submitted by manufacturer) —

| | per cent |
|--|----------|
| Moisture | 5.7 |
| Ash | 1.3 |
| Fat (ether extract) | 21.8 |
| Protein (N \times 6.25) | 49.7 |
| Crude fiber | 1.9 |
| Carbohydrates other than crude fiber (by difference) | 19.6 |
| Starch | none |
| Sugar | none |

Calories—47 per gram 133 per ounce

Uselessness as a Special Purpose Food—Eltola Dietetic Legume Flour is manufactured specially for use in diets restricted in dextrose formers. To be eligible for acceptance, such type of flour shall contain dextrose formers yielding dextrose in an amount not greater than 3.3 Gm per hundred cubic centimeters (the dextrose equivalence being computed as the carbohydrate, plus 58 per cent of the protein, plus 10 per cent of the fat content of the food). Dextrose formers of this legume flour, however, yield many times the quantity of dextrose per hundred cubic centimeters that is permissible for acceptance.

There is authoritative evidence that commercially prepared special diabetic foods such as gluten flour are of limited usefulness to the diabetic patient and that the availability of insulin makes them no longer necessary. Artificial substitutes for ordinary foods are not to be favored, it is much better for the diabetic patient to learn how to plan his diet with foods in common use and readily available. The diet should be exactly prescribed in carbohydrate, protein and fat, and total calories.

The designation of a food as a "diabetic food" merely because it is low in carbohydrates is now unwarranted and misleading and gives the erroneous impression either that the food taken in unrestricted quantities in diabetes is harmless or that it has remedial action. Except for the necessity of restricting foods to avoid overstepping the food tolerance, there are no special diabetic nutritional requirements. The exploitation of starch-free or low carbohydrate foods containing an excess of protein

for use by diabetic patients is unwarranted. Protein may be tolerated almost as poorly, if not quite as poorly, as starch in diabetics.

Because Eltola Dietetic Legume Flour is adjudged without usefulness or special adaptability for inclusion in diets restricted in dextrose formers, it will not be listed among the accepted foods of the Committee on Foods.

ACCEPTANCE WITHDRAWN

RY-KRISP

Manufacturer—Ralston Purina Company, St. Louis

Description—Whole rye wafer, flavored with salt.

Analysis (submitted by manufacturer) —

| | per cent |
|--|----------|
| Moisture | 60 |
| Ash (including added salt) | 37 |
| Fat (ether extraction method) | 20 |
| Protein (N X 6.25) | 13.1 |
| Crude fiber | 2.2 |
| Pentosans | 9.8 |
| Available carbohydrate (by difference) | 63.2 |

Calories—3.2 per gram 91 per ounce

Discussion of Advertising—A booklet and leaflet, abounding with feminine sylph-like figures, proclaiming "Sylvia's message" for exercising and giving "Stay-Slim" menus and newspaper advertising contain the following statements:

"Ry Krip is one of my beauty secrets—says (Madam) Sylvia, Hollywood's miracle worker, the world's foremost authority on beauty. No matter what your beauty problems are—dieting to improve or keep your figure need be no hardship—if you'll remember just one simple thing. Eat Ry Krip regularly. These delicious wafers are made simply of flaked whole rye water and salt—nothing to add superfluous fat only wholesome ingredients which keep you fit and regular. They're an ideal 'stay slim' food—filling but not fattening. That's why Ry Krip has been included for years in the diets I've planned for the movie stars. It's really my assistant in helping you attain greater loveliness. You see I know when you eat Ry Krip regularly you don't want starchy, fattening foods—instead you're getting a food which actually helps you to be slim and stay slim—because it helps to keep you fit."

Sylvia knows that these crisp wafers are marvelously good for staying slim as well. If you want a figure like a movie star eat Ry Krip with every meal they learned by actual experience that these crisp delicious wafers actually keep you slim because they keep you fit! See how soon you begin to feel better—and look better too. If you want to have and keep a perfect figure, exercise properly and eat Ry Krip with every meal! Miss Gloria Stuart, Universal star has discovered that Ry Krip is a pleasant aid to keeping her famous figure at its best. Why Ry Krip helps you to stay slim. Nothing to make you fat—only easily digested ingredients which keep you fit and regular. In fact they keep you from wanting starchy fattening foods. That's why they're so perfect with meals—or between meals. Get the habit of nibbling at a Ry Krip wafer when you're hungry. Eat Ry Krip regularly and watch your waistline waste away. It doubles the joy of dad's favorite beverage—and is good for his waistline too. These crisp delicious wafers are more than a perfect Stay Slim food! Children and grown-ups welcome them because their unique flavor doubles the appetite appeal of any food. For health and enjoyment serve Ry Krip with every meal! Get the Hollywood Habit—exercise regularly, eat sensibly use Ry Krip instead of heavy starchy foods—watch your waistline waste away. Remember when Ry Krip is used instead of heavy starchy foods it's easy to transform many of your favorite menus into successful reducing meals. Ry Krip cuts the calories. Follow the Hollywood habit and eat this delicious Ry Krip you'll get a slim figure. Ry Krip is a safe natural aid to reducing and a wholesome healthful food.

Ry-Krip is an entire rye wafer and as such has essentially the same nutritional values as the entire-grain cereals as a class. It provides a moderate quantity of fibrous material for increasing the indigestible bulk in the intestine, thereby contributing to the roughage necessary for normal bowel functioning. The protein is of good grade biologically, but inferior to milk or meat protein. The high available carbohydrate content contributes food energy for supplying physiologic energy needs. Ry-Krip is essentially a carbohydrate food. The advertising falsely portrays Ry-Krip as possessing specific reducing properties. In fact, Ry-Krip is a rich source of food-energy and taken in any quantity very materially raises the caloric value of the diet. No food has specific reducing properties, especially not Ry-Krip. Ry-Krip will contribute to the production of "superfluous fat" when included in any diet providing greater fuel content than required for meeting food-energy needs. It is no more a "stay-slim" food than bread or many other common foods. There is nothing about Ry-Krip

that will alter one's desire for "starchy, fattening foods" as alleged. It is a "starchy food" contrary to allegations.

Advertising making use of alleged or actual statements of movie stars for instructing the public on scientific nutritional questions does not merit recognition. The eating of Ry-Krip will not make one look better, "keep a perfect figure," or make your "waist-line waste away." Ry-Krip will not give "health" as stated and implied.

The advertising is grossly misinformative and misrepresents the food values of Ry-Krip, its role in the diet, and the relation of any one food or the entire diet to the maintenance or reduction of body weight. Advertising such as this destroys confidence in food advertising in general and promotes misleading advertising practices.

Because of the false misleading advertising, acceptance of Ry-Krip has been withdrawn.

ACCEPTED FOODS

THE FOLLOWING PRODUCTS HAVE BEEN ACCEPTED BY THE COMMITTEE ON FOODS OF THE AMERICAN MEDICAL ASSOCIATION FOLLOWING ANY NECESSARY CORRECTIONS OF THE LABELS AND ADVERTISING TO CONFORM TO THE RULES AND REGULATIONS. THESE PRODUCTS ARE APPROVED FOR ADVERTISING IN THE PUBLICATIONS OF THE AMERICAN MEDICAL ASSOCIATION AND FOR GENERAL PROMULGATION TO THE PUBLIC. THEY WILL BE INCLUDED IN THE BOOK OF ACCEPTED FOODS TO BE PUBLISHED BY THE AMERICAN MEDICAL ASSOCIATION.

RAYMOND HERTWIG Secretary

- 1 FAULTLESS BRAND GOLDEN SYRUP
- 2 JACK SPRAT BRAND GOLDEN SYRUP
- 3 MARSHALL BRAND GOLDEN SYRUP
- 4 UNCLE WILLIAM BRAND GOLDEN SYRUP

Distributors—2 Jack Sprat Foods, Inc., Marshalltown, Iowa.

3 and 4 Marshall Canning Company, Marshalltown, Iowa.

Packer—Marshall Canning Company, Marshalltown, Iowa.

Description—Table syrup, corn syrup flavored with refiners' syrup.

Manufacture—Corn syrup, water and refiners' syrup are mixed, heated to 71 C and sealed in cans.

Analysis (Submitted by packer) —

| | per cent |
|-----------------------------------|----------|
| Moisture | 25.0 |
| Total solids | 75.0 |
| Ash | 0.5 |
| Fat (ether extract) | 0.0 |
| Protein (N X 6.25) | 0.04 |
| Reducing sugars as dextrose | 38.7 |
| Sucrose (copper reduction method) | 9.0 |
| Dextrins (by difference) | 26.8 |

(No methods are available for accurately determining the composition of syrups of this nature, therefore the foregoing analysis is roughly approximate.)

Calories—3 per gram 85 per ounce

Claims of Packer—Recommended for use as an easily digestible and readily assimilable carbohydrate supplement to milk in infant feeding, and as a syrup for cooking, baking and the table.

MARCO BRAND PINEAPPLE JUICE

Distributor—H. A. Marr Grocery Company, Denver

Manufacturer—Alexander & Baldwin, Ltd., Honolulu, Hawaii

Description—Canned, unsweetened pineapple juice retaining in high degree its natural vitamin C content. Same as Greetings Pineapple Juice (THE JOURNAL, Aug 17, 1935, p 513)

STEWART'S BRAND TOMATO JUICE

Distributor—The Jesse C. Stewart Company, Pittsburgh

Packer—Vincennes Packing Corporation, Vincennes, Ind.

Description—Pasteurized tomato juice with added salt, retains in high degree the natural vitamin content. The same as Alice of Old Vincennes Tomato Juice (THE JOURNAL, Feb 20, 1932 p 640)

SATURDAY, NOVEMBER 30, 1935

THYROIDECTOMY FOR HEART DISEASE

Surgery applied to a normal organ, with the intention of altering the general physiologic functions of the body so that a condition in a distant and diseased part may be improved, must rest on a solid foundation. Among recent operative procedures of this nature is ablation of the normal thyroid in certain cases of chronic heart disease. The rationale of this measure rests largely on the work of Dr Herman L Blumgart, who in a series of studies beginning in 1925 was able to show a definite relationship between the rate of blood flow and the thyroid function as measured by the basal metabolic rate,¹ the flow being increased in exophthalmic goiter and slowed in myxedema. Blumgart and his co-workers were thus led to suggest that, when the circulation in decompensated heart disease could not be accelerated by digitalis, rest and other appropriate cardiac therapeutic methods, compensation might be achieved by lowering the circulatory demand through thyroidectomy. Such a procedure should decrease the speed of circulation as the demand is diminished by the falling basal metabolic rate. It would be expected that at some point the crippled supply, as measured by the rate of blood flow, would come into equilibrium with the lowered demand imposed by the thyroidectomy and thus compensation would result. Additional evidence of the rationale has been afforded by clinical observations of a number of patients with decompensated heart disease who were entirely, if only temporarily, relieved of their cardiac failure syndrome by subtotal thyroidectomy.

The failure of persistence of lowered metabolism and clinical cardiac improvement following the subtotal operation introduced total thyroidectomy. The first total ablation of the thyroid for chronic heart disease of nonthyrogenous origin seems to have been performed by Dr David D Berlin² on Dec 15, 1932. During the succeeding six months the metabolic rate

of the patient operated on remained persistently low, averaging minus 28 per cent. The patient was also restored to occupational usefulness in spite of three previous years of complete cardiac invalidism. The special surgical precautions and technic of total ablation of the thyroid have been largely developed and are adequately described by Berlin.

The cardiac indications for complete thyroidectomy are still in process of definition. Congestive heart failure in which prolonged medical management has failed to induce satisfactory results has been considered one of the indications. The selection of patients of this group for operation has been recently discussed by Levine and Eppinger.³ There are some obvious contraindications, such as bacterial endocarditis or active rheumatic carditis. Accompanying renal insufficiency, not dependent on simple passive congestion of the kidneys, and cirrhosis of the liver are other contraindications. They feel in general that, if patients with congestive heart failure are selected at all, it should be done without great optimism. With regard to angina pectoris, the criteria of selection seem to be somewhat more definite. Levine and Eppinger, for example, state that a patient should not be subjected to this operation if able to carry on his occupation. Furthermore, if the patient is unable to work but his financial status permits him to lead a life of leisure, provided he is comfortable, operation would not be advised. Thus the economic and social status of the individual constitute an important element in the selection of patients for operation. There is furthermore no evidence as yet to show that the operation prolongs the life of a patient with angina pectoris, and therefore it cannot be recommended with this in view.

The possible harmful effects of complete thyroidectomy have been mentioned in practically all the discussions. The production of postoperative myxedema is an obvious probability but seems relatively immaterial, since it is possible to minimize effects of this nature by administration of small doses of thyroid extract without apparently undoing the results of lowered circulatory demand. The danger of parathyroid tetany has been insignificant. Even the operative mortality has been satisfactorily low, considering the nature of the procedure and the conditions for which it is performed.

The present status has been assessed by Graybiel and White.⁴ "Complete removal of the thyroid in appropriate cases of angina pectoris has been established as a valuable procedure. Criteria for the proper selection of patients cannot be given categorically, the problem is more individual. It may be stated in general terms, however, that this operation may be considered for

3. Levine S A and Eppinger E. C. Further Experiences with Total Thyroidectomy in the Treatment of Intractable Heart Disease, Am. Heart J 10 736 (Aug) 1935.

4. Graybiel Ashton and White, P D. Diseases of the Heart. A Review of Contributions Made During 1934. Arch. Int. Med 55:842 (May) 1935.

patients for whom medical treatment is unsatisfactory if a sufficient lowering of the basal metabolic rate can be expected and if the patient's fitness for operation can be proved

It is not possible," they say, "properly to evaluate the treatment of congestive failure by complete removal of the thyroid gland

It has been shown that congestive heart failure can be abolished in at least half the patients operated on, and unquestionably most of these patients showed considerable subjective improvement. However, this does not decide the matter. It must be shown that improvement is sufficiently long lasting. A major procedure like total thyroidectomy must promise a comparatively great reward. Even if this operation is successful it must be remembered that the patient faces congestive failure again in a relatively short time with the reexperiencing of previous events. This involves a consideration not only of the patient's wishes but of far-reaching social and economic factors of which the patient is often the poorest judge."

Further conclusion seems, at the present time, unnecessary except that general application of the operation by those unfamiliar with the selection of patients or the surgical technic would seem wholly inadvisable

FOOD VALUE OF ETHYL ALCOHOL

In considering its use for medical purposes, it should be possible to regard alcohol as one would any other therapeutic agent, uninfluenced by views of the use of alcoholic mixtures as a beverage. Although it cannot be doubted that fluids containing alcohol are toxic under certain conditions of dosage, this is not an argument against their use. Almost all drugs are toxic in doses larger than those used for therapeutic measures. Nevertheless, in considering any substance as a therapeutic agent, its physiologic and toxicologic effects must be kept in mind. This is particularly true with respect to alcohol, which, although supplying energy when oxidized, has certain properties, notably its effects on the central nervous system, that militate against its employment.

The ability of the animal body to absorb and oxidize ingested ethyl alcohol was established early¹. There is much controversy, however, regarding the physiologic value of the energy thus made available. The numerous contributions to the subject of the metabolism of ethyl alcohol indicate that when it is ingested it is absorbed unchanged into the circulation, no digestive or breakdown process occurs in the intestine. The rapid rate of absorption of alcohol from the alimentary tract makes it a readily available source of energy to the organism. The therapeutic value of alcohol in collapse rests largely on this attribute. The oxidation of alcohol undoubtedly releases energy, but it has not

been entirely clear whether the energy liberated is dissipated as heat or is available for physiologic work, thus sparing other food materials such as carbohydrate and fat. Suggestions have been made that alcohol in moderate quantities acts like an equivalent amount of fat and carbohydrate, as the addition of alcohol to an already sufficient diet leads to the deposition of body fat and thus to an increase in body weight. Furthermore, alcohol added to a diet otherwise inadequate immediately diminishes the degree of destruction of body protein.

Notwithstanding some indication in the literature that ethyl alcohol has a measurable food value, the unsatisfactory nature of some of the evidence and the contradictory results have left this problem in a controversial state. This has led Mitchell² to conduct a careful and detailed investigation of this question. The practical importance of the problem becomes self-evident in attempts to evaluate the nutritive quality of alcoholic beverages. The subject takes on additional significance in view of the apparently normal presence of alcohol in body tissues and fluids,³ and its possible significance as an intermediary metabolite in carbohydrate metabolism.⁴ In Mitchell's experiments, pairs of rats were fed equal quantities of a good basal diet, one animal of each pair receiving variable supplements of 95 per cent ethyl alcohol. The nutritive effects of the alcohol were measured by determining the growth rates of pair mates over a number of weeks of the experiment and by investigating the nitrogen and energy contents of the tissues formed from an analysis of the carcasses. The investigation included experiments in which supplements of sucrose replaced supplements of alcohol in order to compare the nutritive effects of these two compounds. The comparative effects of alcohol and sucrose supplements on the digestive processes were also studied by chemical examination of the feces of the experimental animals. In one series of experiments the rats were placed in revolving cages equipped with revolution counters, so that the alcohol supplements could be increased in size only as long as voluntary activity was not depressed. In other studies the animals were confined in small compartments with the view of greatly restricting the energy expended on muscular activity and of minimizing any differential expenditure between test and control rats. Careful evaluation of the experimental conditions and critical analysis of the data obtained demonstrated that the energy of ethyl alcohol is to a large extent available for physiologic purposes. When added to a complete diet, alcohol induces more rapid growth and a greater retention of nitrogen and fat. As compared with a similar supplement of sugar, the energy of an alcohol supplement is only about three fourths as available for

4 Shapiro Inez. *J. Biol. Chem.* **108**: 373 (Feb.) 1935.

physiologic purposes, its growth-promoting power is definitely less, though the composition of the new tissues produced is similar in the two instances. Alcohol apparently increased the digestibility of the basal diet, whereas sucrose exerted no appreciable effect in this direction.

These observations of the food value of ethyl alcohol are of considerable interest to the clinician. Although it must be accepted that in recent years the use of alcohol by physicians in the care of their patients has greatly decreased, alcoholic beverages may have a place in rendering more comfortable and peaceful the disturbances of chronic disease and old age. In addition, as a solvent of various medicinal substances alcohol performs a useful function, although the therapeutic rôle in this instance is limited. Even though the uses of alcohol as a therapeutic agent are limited and have largely been replaced by better therapeutic measures, the clear cut establishment of the food value of ethyl alcohol makes available useful information heretofore lacking to the physician.

Current Comment

NONSPECIFIC PROTEIN TREATMENT

In this issue appears the first of two special articles on nonspecific protein treatment, prepared under the auspices of the Council on Pharmacy and Chemistry. Hektoen¹ discusses briefly the nature of the reactions to nonspecific proteins in the treatment of infectious diseases. Next week Cecil² will review experiences and results with this treatment, he shows that modern protein treatment appears to have achieved "a permanent place for itself in modern therapeutics" not only of certain acute and subacute infectious diseases but also in other conditions, notably thrombo-angitis obliterans. To this extent nonspecific protein treatment is a noteworthy achievement in empirical therapeutics of direct interest to the medical practitioner. Both articles point out that the effects of nonspecific proteins in infectious conditions are associated with nonspecific as well as specific anti-infectious processes. Differences in these effects in the same infection and in different infections cannot now be explained satisfactorily. It is evident that much more study of the changes induced by nonspecific proteins in the human body is required in order to obtain more of an insight into the nature and significance of these processes as they occur under various conditions. The opportunities for the investigation of the more intimate nature of the reactions in patients under treatment should not be neglected. In vascular disease, dilatation and release of spasm seem to be responsible for the good effects of protein therapy, but here also is need for closer study. From Cecil's review it appears further that the indications, contraindications and limitations of nonspecific protein

treatment in its present forms are well under way toward fairly definite establishment. Certainly the indiscriminate and offhand use of the treatment is unwarranted and not free from danger.

A NEW SKIN REACTION

Recently Foshay¹ has described a heretofore unrecognized dermal reaction to serum against certain bacterial infections. At the site of the intradermal injection of a small quantity of antiserum a spreading redness develops about a slightly elevated central edema. "The reaction usually appears promptly, within two to four minutes, sometimes less, and rarely not until ten to eleven minutes, and is usually from 3 to 5 cm in diameter at the end of twenty minutes, sometimes larger. It is usually maximal in from twenty to twenty five minutes after injection of the serum, and there is very often an intensification of the reaction after about six hours. Urticaria never occurs at any time, and only very rarely have any of these reactions been accompanied by itching. The erythema, however, is often intense and may spread rapidly. No constitutional symptoms accompany this local reaction. The initial erythema commonly lasts for only half an hour or so and then fades rapidly. This reaction has been seen only when a patient with a given bacterial infection has been skin tested with an antiserum specific for that infection. When individuals exhibit this simple erythematous-edematous reaction to the specific homologous antiserum, control injections of normal serum from the same animal species, and of antisera specific for other infections, made from the same species, elicit no reactions whatever. Hence this E-E [erythematous-edematous] reaction is obviously unrelated to the phenomena of serum protein sensitization." The new reaction has been observed in tularemia, brucellosis, tuberculosis, inguinal lymphogranuloma and typhoid, and in streptococcal, staphylococcal and gonococcal infections, but no definite statements are ventured as yet as to its frequency except that in tularemia it seems to be practically constant. It appears to concern a specific reaction between substances in the antiserum, most likely antibodies, and substances in the skin of the patient, most likely of antigenic nature, and consequently it may prove to be of diagnostic value. In typically positive form as well as when wholly negative the test may serve also to exclude sensitiveness to the antiserum injected. Foshay points out that the reaction has been and may be misinterpreted as a response to serum sensitiveness and thus lead to needless delay and difficulties in the administration of antiserum. He emphasizes that the absence of urticaria clearly distinguishes the new reaction from the reaction to serum sensitiveness. It will be of interest to watch the further developments in connection with this newly described skin phenomenon and, if Foshay's work is confirmed, its occurrence in various diseases, together with its significance and mechanism.

Association News

COMMITTEE TO STUDY CONTRACEPTIVE PRACTICES AND RELATED PROBLEMS

Dr Everett D Plass of Iowa City has been elected to membership on the Committee on Contraceptive Practices and Related Problems instead of Dr James R. McCord of Atlanta, Ga, who declined to serve because of insufficient time to devote to the work of the committee. Dr Carl Henry Davis was elected chairman of the committee. The committee as at present constituted consists of Drs Carl Henry Davis, Milwaukee, chairman, George W Kosmak, New York, W A Coventry, Duluth, Minn., Richard J O'Shea, Seattle, John Rock, Boston, Willard Richardson Cooke, Galveston, Texas, and Everett D Plass, Iowa City, with Drs James R. Bloss and W C. Woodward, ex officio

RADIO BROADCASTS

The American Medical Association broadcasts over the Blue network and certain additional stations of the National Broadcasting Company at 5 p m eastern standard time (4 o'clock central standard time, 3 o'clock mountain time, 2 o'clock Pacific time) each Tuesday, presenting a dramatized program with incidental music under the general theme of "Medical Emergencies and How They Are Met." The title of the program is "Your Health." The program is recognizable by a musical salutation through which the voice of the announcer offers a toast "Ladies and gentlemen, your health!" The theme of the program is repeated each week in the opening announcement, which informs the listener that the same medical knowledge and the same doctors that are mobilized for the meeting of grave medical emergencies are available in every community, day and night, for the promotion of the health of the people. Each program will include a brief talk dealing with the central theme of the individual broadcast.

The next three programs are as follows

- December 3 Tuberculosis Morris Fishbein MD
- December 10 Hunting Accidents Morris Fishbein MD
- December 17 Animal Diseases in Man, W W Bauer, MD

This program is broadcast also on the short waves through KDKA, Pittsburgh, over station W8XX, 11,870 and 12,210 kilocycles

Medical News

(PHYSICIANS WILL CONFER A FAVOR BY SENDING FOR THIS DEPARTMENT ITEMS OF NEWS OF MORE OR LESS GENERAL INTEREST SUCH AS RELATE TO SOCIETY ACTIVITIES, NEW HOSPITALS, EDUCATION, PUBLIC HEALTH ETC.)

CALIFORNIA

"Science Edits the News"—At the request of Station KYA, the San Francisco County Medical Society now broadcasts exclusively over that station a program entitled "Science Edits the News." Before the first of the year the station is expected to increase its power to give the program full Pacific Coast coverage. The chief purpose of the program is to give the public facts in an ethical manner concerning newspaper items related to medicine and its allied sciences. It will be presented each Tuesday from 6 to 6 15 p m until further notice.

Group Insurance Against Malpractice—The report of a committee appointed several months ago to investigate proposals of group malpractice insurance for members of the Los Angeles County Medical Association was accepted by the board of councilors, November 4. The report recommended that the association take steps to secure group insurance against malpractice and form a permanent committee on malpractice and expert testimony. It was further suggested that the council recommend to the board of trustees such increase in the annual dues as is necessary to finance a group policy.

Deaths from Poison in Baking Soda—Three deaths in San Francisco have been attributed to poisoned baking soda, according to a warning broadcast over the radio, November

19, by Dr Jacob C Geiger, city health officer. Seventeen other persons in the city were reported to be violently ill when they ate food in which the soda was used or partook of it for medical purposes, it was stated. These cases were all traced to salvaged sodium bicarbonate sold retail by one store. Apparently salvage agents sold six barrels, and at least one barrel contained sodium fluoride, which mixed with the soda. Arsenic also was found in some samples analyzed, but its source as yet remains unexplained.

Society News—At a meeting of the Los Angeles Society of Ophthalmology and Otolaryngology, November 25, a symposium on corneal ulcer was presented by Drs Melvorton E. Trainor, William A Boyce and Alexander Ray Irvine.—The Los Angeles Society for Neurology and Psychiatry was addressed, November 20, by Bennett M Allen, PhD, and Lawrence Gahagan, PhD, both of the University of California, Los Angeles, on "Experiments with the Hypophysis" and "Intelligence and Personality Studies in Epileptic Children," respectively.—Dr Bruce M Stephens, Alameda, discussed "Emergency Treatment in Common Eye Disorders" before the Alameda County Medical Association, November 18, and Dr Theodore C Lawson, Oakland, "Carcinoma of the Colon and Rectum"—At a meeting of the Sonoma County Medical Society in Santa Rosa, October 20, speakers included Dr William B Faulkner Jr, San Francisco, on surgery of the chest.—Dr Henry Schmitz, Chicago, presented a paper before the Los Angeles County Medical Association, November 7, entitled "How May the Prognosis and Curability of Cancer Be Improved?"

COLORADO

Personal—Dr Marion F Haralson, senior surgeon, U S Public Health Service, is now acting secretary of the Colorado State Board of Health, in the absence of Dr Roy L Cleere, Denver, who is at the School of Health Administration of Johns Hopkins University, Baltimore, for a year's study.

Society News—At a meeting of the Crowley County Medical Society, October 11, in Ordway, speakers were Drs John V Ambler, Denver, and William C Service, Colorado Springs on "Acneiform Eruptions" and "Eczema, Hay Fever and Asthma," respectively.—A symposium on tuberculosis was presented before the Garfield County Medical Society in Glenwood Springs, October 21, by Drs George P Bailey, Edgewater, and John Zarit, Denver.—Dr George K Cotton, Denver, discussed "Internal Derangements of the Knee Joint" before the Larimer County Medical Society in Fort Collins, October 2.—The Mesa County Medical Society devoted its meeting in Grand Junction, October 15, to a symposium presented by the team representing the committee on tuberculosis education of the state medical society, speakers were Drs Charles O Giese and John B Crouch, Colorado Springs.—Dr Cyrus W Anderson, Denver, delivered a paper and showed a motion picture on "Physiology of Fertilization in the Human Female" before the Pueblo County Medical Society in Pueblo, October 15.—At a meeting of the Otero County Medical Society in October, Dr Harold R McKeen, Denver, discussed "Fractures In and Around the Elbow" and Dr Atha Thomas, Denver, "Fractures of the Ankle."

ILLINOIS

Malaria Control Program.—Work was recently started on a program of malaria control in southern Illinois, where the disease is widely prevalent, according to the state health department. This is a WPA project, under direct supervision of the health department. Swampy areas in the malaria infected territory will be drained and the banks of lakes, streams and other natural bodies of water will be cleared to dry up mosquito breeding places and to make practicable the use of oil and minnows in controlling the propagation of insects.

Southern Illinois Meeting—The sixty-first annual meeting of the Southern Illinois Medical Association convened in Belleville, November 7-8. Speakers included the following

- Dr William E. Leighton, St Louis, Division of the Anterolateral Tracts of the Spinal Cord for Relief of Pain
- Drs Albert B McQuillan and Wendell Stewart, East St. Louis, Calcification of the Collateral Ligaments of the Knee
- Dr Charles Hugh Neilson, St. Louis, Effect of the Weather on Human Conduct and Disease.
- Dr Charles B Reed, Chicago, The Social Security Act and the Doctors
- Dr John W Thompson Jr., St. Louis, Pyloroplasty in the Treatment of Duodenal Ulcer
- Dr Frank P McValley, St Louis, The Obstetrics of General Practice.

Dr James S Templeton, Pinckneyville, was named president at this session and Dr Harvey Felts, Marion, secretary

Chicago

Society News—The Chicago Orthopedic Society was addressed, November 8, by Dr Hiram Winnett Orr, Lincoln, Neb., on "Best Methods of Reduction and Fixation in Open Infected Fractures", Stewart H Crossland, Gary, Ind., "Acute Suppurative Arthritis," and Mrs Davis G McCarn, "The Work of the Illinois Society for Mental Hygiene"—The North Side Branch of the Chicago Medical Society was addressed, November 7, by Surg Gen. Charles R. Reynolds and Dr Raymond O Dart, assistant curator, Army Medical Museum, Washington, D C., on "Employment of the Medical and Allied Professions of the Military Service in a National Emergency" and "Scientific Research in the United States Army," respectively—A symposium on obstetrics was presented before the Chicago Medical Society, November 20, speakers included Drs Stewart H Clifford, Boston, and, from Chicago, Philip A Daly, Frederick H Falls, Edward D Allen and Eugene Cary

The Late Dr LeCount Donor of Capps Prize—At the meeting of the board of governors of the Institute of Medicine of Chicago, October 22, it was unanimously voted to enroll the late Dr Edwin R. LeCount as a benefactor of the institute in recognition of his gift in 1931 of \$10,000 for a trust fund to bear the name of Dr Joseph Almarin Capps. The income was to be used to establish an annual prize for the most meritorious investigation in medicine in Chicago completed within two years after graduation by a graduate of a medical school in Chicago. The donor of the fund has until this time remained anonymous. Four prizes of \$500 each have been awarded since the fund was established. Dr LeCount was professor of pathology in Rush Medical College from 1892 until his death. He was a member of the House of Delegates of the American Medical Association in 1903 and served as chairman of the Section on Pathology and Physiology in 1920-1921. Dr Capps is clinical professor of medicine at the Division of Biological Sciences, University of Chicago.

Maximum Sentence Imposed on Barron—Kenneth Barron, operator of the Madison-Western Clinic, 2418 Madison Street, was sentenced to one year in the county jail and fined \$500, November 14, by Municipal Judge Erwin J Hasten, who found him guilty of practicing medicine without a license, newspapers reported. The penalty is the maximum on this charge. Barron's motion for a new trial was overruled, but the judge granted him a stay of mitimus for sixty days to allow time for an appeal. His bond was increased from \$2,000 to \$5,000 on recommendation of Assistant State's Attorney Sheer, prosecutor in the case. When he was unable to supply this bond, Barron, who is a former barber, went to jail. In imposing sentence, Judge Hasten said "Quack doctors are death dealers and a menace to the reputable medical profession. In reality, they prevent ignorant, gullible persons from getting the services of competent physicians. Instead of healers they become killers indirectly." The Madison-Western Clinic advertised its cut-rate prices in various newspapers. It was admitted that one death occurred at the clinic—a woman died during a tonsillectomy. This evidence was ruled out by Judge Hasten because it was barred by the statute of limitations, eighteen months having elapsed between the performance of the operation that caused the death and the filing of the complaint on October 8. A second charge against Barron, that of operating a clinic without a license for practicing medicine, was continued until November 21. It was Judge Hasten who a few months ago imposed a maximum sentence on an illegal practitioner, Raphael Lee (THE JOURNAL, June 22, p 2272).

IOWA

Carbon Monoxide Responsible for Twenty Deaths—Accidental poisoning attributed to carbon monoxide caused twenty deaths in Iowa during 1934, according to the state department of health. Ten of the deaths were caused by exhaust gas from automobiles, five fatalities taking place in home garages. The state department emphasizes in its bulletin that carbon monoxide poisoning constitutes a serious health problem. In poorly ventilated public garages, concentration of the gas may reach the dangerous level of 10 parts per 10,000 parts of air near the exhausts of cars which are kept running. In a street with heavy traffic, the concentration may exceed 1 part per 10,000 parts of air.

Society News—Dr William W Bauer, Chicago, addressed a joint meeting of the Wapello County Medical Society and the Kiwanis and Rotary clubs November 4, in Ottumwa on "Health Education versus Health Racketeering"—The Iowa Society for Crippled Children was organized at a meeting, November 1, in Des Moines, Gerald Hunt, Gutenberg, past district governor of Rotary International, was named temporary

president, and Miss Bess Johnson, principal of Smouse School, Des Moines, temporary executive secretary—Dr Arthur E. Hertzler, Halstead, Kan., will discuss "Diagnosis and Treatment of Uterine Hemorrhages" before the Linn County Medical Society in Cedar Rapids, December 12.

MAINE

Society News—Speakers before the Aroostook County Medical Society at Mars Hill, October 22, included Drs Oscar Norell, Caribou, "Our Present Organization and the Health Insurance Problem" and William B Grow, Presque Isle, "State Medicine of Great Britain."—Dr Siegfried Thannhauser, Boston, addressed the Oxford County Medical Society in Bethel, October 15, on functional tests of the liver and dietetic treatment of liver diseases.

MASSACHUSETTS

Fifth Medical Pageant—The fifth medical historical pageant was presented by students of Tufts College Medical School at the Boston Medical Library, November 18, under the auspices of the Boston Medical History Club. A display of manuscripts and books dealing with the characters in the play was arranged by James F Ballard, director of the library. The theme of the pageant was the "Story of Early Medicine in Massachusetts," divided into three epochs: the Colonial (1620-1700), the Pre-Revolutionary period (1700-1775), and the Post-Revolutionary period (1775-1846).

Opposition to Sale of Strychnine—The Massachusetts Medico-Legal Society adopted a resolution, October 2, discountenancing the sale or dispensing of strychnine in any form that covers or conceals its taste or in a container that is not clearly labeled as to name, amount in each dose, warning of "poisoning" if dosage is exceeded, and treatment if excess is accidentally taken. The society took this action in view of the many fatalities that have occurred among children who have been attracted to the candied coatings of the drug, either by itself or incorporated with other drugs in laxative and tonic tablets.

MICHIGAN

Coldwater School Becomes "Children's Village"—The Michigan Children's Village for care of children of the higher grades of mental deficiency has been established at Coldwater, occupying buildings formerly used by the Michigan State Public School. While these children will be gradually moved from the Michigan State Home and Training School at Lapeer, the village is not a branch of this institution, but a separate state organization. Recent legislation provided for the establishment of the Michigan Children's Institute at Ann Arbor to be used as a receiving home for dependent and neglected children formerly maintained at the Michigan State Public School. The institute will care for these children until private homes are found for them. Ann Arbor was selected because the University Hospital can give the medical and psychologic examinations necessary for successful placement. The children's village is expected ultimately to shelter between 300 and 400 mentally deficient children, while the institute will maintain quarters for only about thirty of the dependent children. Dr Harry A. Schneider, formerly assistant superintendent of the Michigan Home and Training School at Lapeer, has been appointed superintendent of the Michigan Children's Village.

MISSOURI

Society News—Dr Walter Freeman, Washington, D C., discussed "The Organs of the Endocrine System and Their Relation to Personality" before the Jackson County Medical Society, Kansas City, November 19—A symposium on gastrointestinal diseases was presented before the St. Louis Medical Society, November 5, by Drs Frank D Gorham, Joseph W Larimore, Leroy Sante and Louis Rasseur. At a meeting, November 12, Dr Adrien S Bleyer discussed "The Role of the Parasympathetic Nervous System in True Enuresis," and H Tsuchiya, Sc.D., "Intestinal Parasitism."

Tuberculosis Conferences—The health division of the department of public welfare of St. Louis announces the fourth annual series of tuberculosis conferences, the first of which, December 5, will be devoted to a symposium on the diagnosis of tuberculosis. The second, December 9, will be given over to demonstrations in health centers. A symposium on tuberculosis will make up the third conference, December 12, and the last will be a demonstration clinic at Koch Hospital, December 16. Announcement is also made of a course in maternal hygiene, to be held December 4, 11 and 18, and one on child hygiene, December 3, 6 and 10.

NEVADA

State Medical Meeting and Election—Dr Charles E. Secor, Elko, was chosen president elect of the Nevada State Medical Association at the annual meeting in Elko, October 25-26, and Dr Richard O. Schofield, Boulder City, was installed as president. Dr Horace J. Brown, Reno, was reelected secretary, and Reno was chosen for the meeting place in September 1936. The program was as follows:

Dr Lorenzo Dow Inskeep, Medford, Ore., *Etiologic Factors in Epilepsy and Their Treatment*
Dr Clarence Eliot Snow, Salt Lake City, *Branchial Cysts and Lateral Cervical Fistulae*
Dr Edward S. Pomeroy, Salt Lake City, *True Status of Electro-removal of the Prostate with the Endoscope*
Dr Charles W. Mayo, Rochester, Minn., *Unilateral and Bilateral Hernia: A Comparative Study of Postoperative Complications*
Dr Alfred W. Adson, Rochester, Minn., *Treatment of Dysmenorrhea*
Dr George A. Cochran, Salt Lake City, *Medical Management of Peptic Ulcer*
Dr Ralph C. Pendleton, Salt Lake City, *Treatment of Major Burns*
Dr John A. Fuller, Reno, *Common Eye Affections*

NEW JERSEY

The Harrison S. Martland Lecture—The Essex County Anatomical and Pathological Society has initiated a yearly lecture in honor of Dr Harrison S. Martland, medical examiner of Essex County and associate professor of forensic medicine at New York University College of Medicine. The first Harrison S. Martland Lecture will be given December 14 at the Academy of Medicine of Northern New Jersey, Newark, by Dr George H. Whipple, dean, University of Rochester School of Medicine and Dentistry, Rochester, N. Y., on "Problems in Anemia." Dr Whipple will be introduced by Dr Emanuel Libman, New York.

NEW YORK

Low Maternal Mortality Rate—Recent figures compiled by the state department of health show that the maternal mortality rate in New York in 1934 (50.6 per 10,000 total births) was the lowest ever recorded except in 1916. The 1933 rate was 60.9. The greatest decrease took place in New York City and a slight increase appeared in rural areas. There were 979 deaths in the entire state, compared with 1,190 in 1933. In 1934 there was an increase in deaths from puerperal hemorrhage and toxemias of pregnancy, but those from other puerperal causes were the lowest in several years.

New York City

Queens General Hospital Opened—The first municipal hospital in the Borough of Queens, the Queens General Hospital, was opened, October 30, with a ceremony at which Mayor La Guardia was the principal speaker. The 600 bed institution was begun in 1931. PWA grants amounting to \$800,000 were made available late in 1934 for the installation of plumbing and equipment. The entire cost of the plant was \$3,845,000. A comprehensive clinical organization has been set up. It has a visiting staff of 234 and thirty-seven interns and residents. Dr Carl Boettiger is president of the medical board and Dr Marcus D. Kogel, formerly medical superintendent of Cumberland Hospital, is medical superintendent.

OREGON

Firm Attempts to Dupe Physicians—The Portland Better Business Bureau has issued a report on the "W. B. Mayo Laboratories," which recently appeared in Oregon, apparently from California. It advertises a nostrum known as "Dr. W. B. Mayo's Formula" for overacidity. The attention of the bureau was directed to the concern whose address is given as Medford, by an advertisement in Portland newspapers asking for men to represent a "nationally known corporation." Men who answered the advertisement were offered positions to call on physicians as representatives of a pharmaceutical firm. The salesman's job was to induce the physician to become a consultant for the firm and pay it \$200. In return for this investment, the consultant would receive a proportionate part of 5 per cent of the profits of the company in the state; the bureau points out that, if 5,000 physicians contributed and the firm sold \$1,000,000 worth of products in a year, it would still take twenty years for the physician to get his money back. It was also represented that the physician would receive patients attracted through a radio program. According to the Better Business Bureau of Los Angeles, where the concern appears to have an office at 3733 Wilshire Boulevard, the firm plans to spend \$1,000,000 in radio advertising in which it will be stated that "the W. B. Mayo Laboratories will gladly suggest a reputable physician in your community." Of course the physician would be one who had invested \$200 in the business; the report points out. According to records of the American Medical Association, Woodward Bruce Mayo was born in Salt Lake City in

1891 and holds a diploma issued by Loyola University School of Medicine, Chicago, in 1917. He was licensed to practice in California in 1921 and his license was revoked in 1931 following a hearing on charges based on an illegal operation. His license was restored Feb. 27, 1933, and he was placed on probation for five years. Last February he was brought before the California board of medical examiners and it was decided that he should be cited to appear at the board's July meeting to show cause why his license should not be revoked again. In the meantime he disappeared from California. The Portland bureau adds that the concern failed to file a report and pay a license fee to the state corporation department for the fiscal year ended June 30.

PENNSYLVANIA

Graduate Assembly—The Montour County Medical Society presented its first graduate assembly for the winter season at Geisinger Memorial Hospital, Danville, November 15. Guest speakers were Drs. Russell L. Cecil, New York, on "Types of Pneumonia and Their Treatment by Serum" and "Etiology and Treatment of Chronic Arthritis," and Vaughn C. Garner, Philadelphia, on "Some Common Dermatological Problems" and "Diagnosis and Treatment of Early Syphilis."

Philadelphia

Women's Conference on Cancer Research—The Woman's Auxiliary of the Lankenau Hospital Research Institute for the Promotion of Cancer Research held its third annual conference on research in cancer, November 12, at the Century Club. Dr. Francis Carter Wood, New York, spoke on "What Progress in Cancer Research?" Mrs. Marjorie B. Illig, representing the American Society for the Control of Cancer, New York, "The Challenge of the Day," Mrs. John J. H. Phillips, chairman of the division of public health, State Federation of Pennsylvania Women, "Local Signs of Progress in Cancer Control," and Dr. Stanley P. Reimann, director of the Lankenau Hospital Research Institute, "Cancer Prevention."

Society News—Dr. John L. Rice, health commissioner of New York City, delivered the James M. Anders Lecture of the College of Physicians of Philadelphia, November 6; his subject was "Looking at Tuberculosis, Cancer, Diabetes, Heart Disease and Syphilis from the Public Health Point of View."—A symposium on pulmonary disease was presented before the Philadelphia County Medical Society, November 27, by Drs. Claude P. Brown, Isadore Kaufman, Eugene P. Pendergrass and Gabriel Tucker.—Speakers at a meeting of the Philadelphia Pediatric Society, November 12, were Drs. Robert T. Devereux, West Chester, "The Use of Liver Extract in the Treatment of Infection," Herman Gold, Chester, "Studies on Whooping Cough Prophylactic Immunization," and Sidney Weiss, "Enuresis: A Statistical and Analytic Study."—Dr. Jean R. Oliver, Brooklyn, addressed the Pathological Society of Philadelphia, November 14, on "The Abnormal Nephron of Chronic Hemorrhagic Bright's Disease."—Dr. Warren T. Vaughan, Richmond, Va., will address a joint meeting of the North End Medical Society and the North Branch of the Philadelphia County Medical Society, December 19, on "Methods in the Study and Treatment of Food Allergy."

Pittsburgh

Society News—Externs of Western Pennsylvania Hospital held their third annual reunion at the hospital in October. Dr. George P. Muller, Philadelphia, gave the principal address on proper uses and types of anesthesia.—Drs. John W. Shirer and George J. Wright addressed the Pittsburgh Academy of Medicine, November 12, on "Hyperthyroidism—Other Factors in Its Interpretation" and "Multiple Sclerosis Syndromes" respectively.—Speakers at a meeting of the Allegheny County Medical Society, Pittsburgh, November 19, were Drs. Ralph R. Mellon on "Bacteriology of Common Colds," Ehrhardt Ruedemann, "Sinus Ear and Mastoid Infections Following Common Colds," and Charles J. Bowen, "Treatment of Common Colds," and Carlton E. Brown, Sc.D., of the U. S. Bureau of Mines, "Dust Respirators." The bureau of mines sponsored a scientific exhibit.

VIRGINIA

Society Elections—The Virginia Pediatric Society at a meeting in conjunction with the annual meeting of the Medical Society of Virginia in Norfolk, October 15-17, reorganized and elected the following officers: Drs. Basil B. Jones, president, John S. Weitzel, vice president, and W. Ambrose McGee, secretary, all of Richmond. The Virginia Urological Society met at the same time and elected the following officers: Drs. Joseph F. Geisinger, Richmond, president; Charles J. Devine, Norfolk, vice president, and Linwood D. Keyser, Roanoke, secretary.

WISCONSIN

Society News—Mr J George Crownhart, executive secretary of the State Medical Society of Wisconsin, addressed a joint meeting of the Racine and Kenosha county medical societies in Kenosha, October 29, on state medicine and health insurance.—Dr Cleveland J White, Chicago, addressed the Fond du Lac County Medical Society, Fond du Lac, in October, on diseases of the skin, with special reference to ringworm, acne, impetigo and eczema.—Speakers before a meeting of the ninth councilor district of the State Medical Society of Wisconsin in Wausau, October 30, were Drs John S Lundy, Rochester, Minn, on anesthesia, Walter C Frenzel, Wausau, dextrose and its uses, and Gregory G Shields, Abbottsford, trichinosis.—The Milwaukee Neuropsychiatric Society visited Madison for a meeting, October 31, speakers were members of the faculty of the University of Wisconsin Michael F Guyer, Ph D, on "The Human Constitution as the Biologist Sees It", Dr Elmer L Sevringhaus, "The Present Status of the Endocrine Glands," and Dr William A Mowry, "Allergy and the Central Nervous System"—The Milwaukee Society of Chemical Surgery met, November 26, to hear the following speakers Drs Alexander R Colvin, St. Paul, on "Fracture Problems", Frederic Christopher, Evanston, "Inflammatory Tumors of the Cecum Simulating Appendicitis," and Robert I Hiller, "Postoperative Anuria."—Drs Donald K Bacon and Joseph F Borg, St. Paul, addressed the Barron-Washburn-Sawyer-Burnett Counties Medical Society, Cumberland, October 29, on "Indications for and Uses of Blood Transfusion" and "Diagnostic Significance of Abdominal Pain," respectively

GENERAL

In Memory of Dr Wiley—Walter Hoge MacIntire of the department of chemistry at the Agricultural Experiment Station, University of Tennessee, gave the fifth Harvey W Wiley memorial address of the Association of Official Agricultural Chemists at the annual meeting November 11 in Washington, D C Dr Wiley was a founder and the first president of the association

Industrial Hygiene Journal Changes Name—The *Journal of Industrial Hygiene*, edited at the Harvard School of Public Health, Boston, announces that in 1936 it will take the name *Journal of Industrial Hygiene and Toxicology*. It will resume its former publishing schedule of ten issues a year instead of six and the content of original papers will be increased about 50 per cent.

Annual Tuberculosis Seal Sale—The twenty-ninth annual sale of Christmas seals by the National Tuberculosis Association and its constituent state and local societies opened November 29 and will continue till Christmas. The 1935 seal shows a girl of about 1860, designed as a reminder of the time when "consumption" was accepted as a plague whose victims were doomed. The sale of seals increased 5 per cent in 1934 over that for the preceding year, the first increase since 1929. The association recently announced that its monthly bulletin is to be expanded to publish

brief articles, abstracts from other health periodicals, book reviews and news of tuberculosis activities

Influenza Virus Desired for Study—The Hospital of the Rockefeller Institute for Medical Research, New York, announces that staff investigators studying the virus of influenza are anxious to obtain new strains for study and comparison with those previously studied. Strains of a filtrable virus apparently having an etiologic significance have been recovered from several localized epidemics in Puerto Rico, Philadelphia and Alaska. The Rockefeller Foundation has requested state and city health officers to cooperate with the hospital. Dr Rufus Cole, director, asks that health officials notify him by telegram collect of any outbreak of typical influenza, that he may take steps to collect the desired material.

Health Officials Tour Country—Seven foreign health officials are guests of the U S Public Health Service in a tour of the United States to study new medical developments under the American social security program. The tour has been arranged by the League of Nations, and the itinerary includes New York, Washington, Baltimore, Knoxville, Tenn, Cincinnati, Chicago, Albany, N Y, Boston and New Haven. Included in the party are Dr L S Fridericia, professor of hygiene, University of Copenhagen, Dr J Parisot, professor of hygiene, University of Nancy, Prof R M F Picken, Welsh National School of Medicine, Cardiff, Dr Einar Rietz, chief medical officer of health Stockholm, Dr H van der Kaa,

chief health officer of the Netherlands, Dr Frank G Boudreau of the League of Nations, and Dr B Boric, chief of the health service, Yugoslavia.

Annual Report of American Red Cross—Seven hundred and sixty-five Red Cross nurses made 1,156,003 visits to 214,444 patients during the year ended June 30, 1935, according to the annual report of the American Red Cross. This represents an increase of 39 per cent over the previous year. Of the 633,944 school and preschool children inspected by the nurses, 325,329 were found to be suffering from one or more physical defects, 195,137 were treated by Red Cross or cooperating physicians. Immunization against diphtheria was a major project in many of the Red Cross chapters, more than 54,700 children being immunized, most of them of preschool age. Between 25,000 and 30,000 persons received treatment for pellagra. An increasing number of mothers and young women are taking courses in home hygiene and care of the sick, it was stated, 52,196 persons having completed this course in the past year. The Will Rogers Nursing Fund, established in 1934 through a gift of \$25,000 by the late Mr Rogers, assisted in supporting public health services in fifty-seven communities of twenty-seven states. Special emphasis was placed on malnutrition, especially among children, and in San Luis Valley, in southern Colorado, an oral hygiene project was inaugurated as the result of a large outbreak of Vincent's infection. There were 128 domestic disasters in which the Red Cross extended aid during the year, exceeding by forty six, or 56 per cent, the average number of disasters annually requiring Red Cross assistance during the past ten years. Not only was the year heavy in the number of disasters, the report stated, but the geographic distribution was wide, with thirty-seven states affected in addition to the territory of Alaska, 110,000 persons were aided in these disasters. The total expenditures during the year amounted to \$2,945,644.13. March 1, Admiral Cary T Grayson took over the duties of chairman, succeeding Judge John Barton Payne, who died in Washington, January 24, within two days of his eightieth birthday.

Medical Activities of Rockefeller Foundation—The annual report of the Rockefeller Foundation shows that, of \$12,679,775 expended in 1934, \$1,026,200 was appropriated for the medical sciences and \$2,200,000 for public health activities. In the medical field emphasis was placed on advancement of neurology and psychiatry, for which aid of four types was provided: grants to universities and institutions for development of research and teaching, endowment and building funds for establishing departments of psychiatry, grants to individual investigators in mental disease, and fellowships to enable men and women to obtain advanced training. In public health the foundation engaged in field research on yellow fever, undulant fever, malaria, hookworm disease, tuberculosis, vaws and diphtheria, conducted yellow fever surveys and control campaigns, carried out malaria control projects, supported demonstrations of public health programs, aided in organizing or maintaining health departments, and contributed to the training of public health personnel through direct fellowships and aid to schools and institutes of public health and hygiene. Yellow fever research has demonstrated that there are two endemic areas in the world, one in West Africa and the other in the Amazon Valley of South America. It has also come to be recognized that yellow fever may be transmitted by vectors other than the stegomyia mosquito, a discovery that opens new problems to the investigator. In addition to these two principal divisions, the foundation appropriated \$1,051,210 for the natural sciences, with specific concentration in experimental and physicochemical biology. President Max Mason indicated in a statement accompanying the report that in the immediate future emphasis will be placed on special fields and realistic research designed to meet definite and clearly recognized needs. It will continue its traditional work in public health, the major interest in medical science will continue to be mental health, and in the natural sciences support will be given to studies in the broad field of modern analytic biology, directed toward the understanding of physical and mental growth and development.

FOREIGN

Nobel Prize in Chemistry Awarded to the Joliot's—The Nobel prize in chemistry was awarded, November 14, to Prof. Frederick Joliot and his wife, Mme Irene Curie Joliot, a daughter of the late Pierre and Marie Curie, discoverers of radium, for their synthesis of radioactive elements. They have succeeded in creating radium substitutes by bombarding atoms of ordinary chemical elements with alpha rays to make them radioactive. The Nobel prize was awarded to Madame Joliot's parents in 1903 for their joint discovery of radium and again to her mother in 1911 for her isolation of the element.

McDonnell Library Opened—The Aeneas McDonnell Library at the Toowoomba General Hospital, Toowoomba, Queensland, Australia, was officially opened September 14. Dr. McDonnell, chief surgeon at the hospital for forty-six years, recently donated his medical library of about 300 books to the hospital, which arranged a special room for it. At the opening ceremony Dr. McDonnell announced his retirement from the active staff. Dr. McDonnell was born in Australia in 1864 and graduated from the University of Sydney. He has been a member of the Medical Board of Queensland since 1909.

Rockefeller Gift to London Hospital—A gift of £60,000 to the National Hospital, Queen-square, London, for new buildings has been announced by the Rockefeller Foundation, with the condition that the hospital authorities raise £120,000 more, the remainder of the amount needed for the new construction. The foundation has offered another £60,000 toward an endowment fund for research, to be available for remuneration of workers. Plans include new teaching rooms, laboratories with special wards, and a new surgical department. National Hospital was the scene of much of the work of Hughlings Jackson, the great neurologist, and has long been recognized as a center for the study of neurology.

Government Services

Annual Report of Food and Drug Administration

During the fiscal year ended June 30, the Food and Drug Administration made 2,011 seizures and 1,029 prosecutions, both slightly larger than the corresponding figures for the previous year. More than 60,000 samples were collected and examined, nearly 50,000 of which were foods. These samples represent the output of more than 13,000 manufacturers, 3,000 of whom were responsible for some form of violation. The report points out that a definite plan of sampling is used, applied in the same manner in all inspection districts.

Violations are classified in three principal groups: practices constituting menaces to public health, adulterations involving contamination of foods with filth and decomposition, and economic cheats. Those in the first group, being obviously most important, take more time than any other effort. Of this type, spray-residue inspections are the most important single regulatory activity. The administration analyzed 6,331 samples from 3,300 producers, 338 seizures were made, 299 of which were apples. The largest number of these were in the Great Lakes and Mississippi Basin states.

The government inspectors investigated seventy-three outbreaks of food poisoning, including seven diagnosed as botulism, but there was no case of botulism from domestic supplies of commercially canned food. A notable fact was that not a single can of the salmon packed during the year was seized. In this connection may be mentioned administration of a new law adopted by Congress in 1934, providing that packers of sea food might apply for government inspection of their processes, the packer to bear the expense.

An unusual development was the seizure of old and deteriorated drugs, which unscrupulous brokers took in trade and tried to work off. Products were found that had been on shelves since before the enactment of the Food and Drugs Act. These dealers were especially active in Texas, where authorities destroyed twenty-eight tons of dangerous old stocks.

Medicinal preparations bearing false and fraudulent claims formed the basis of 177 seizures, of which 174 products were referred to the Solicitor General for prosecutions. Drug preparations other than proprietary medicines and medicinal whiskey accounted for thirty-nine seizures, misbranded antiseptics two, alleged reducing substances four and products misbranded for vitamin claims six. A total of 2,298 samples of products recognized in the U. S. Pharmacopeia and the National Formulary were taken, of these, 1,958 met the requirements of the standards. Extensive sampling of anesthetic ether was continued, of 1,790 individual containers examined, only six failed to meet the requirements of the Pharmacopeia. A few seizures were made of other types of anesthesia. During the fiscal year 2,500 notices of judgment describing terminated actions were published. Penalties imposed ranged from 1 cent to \$4,500, the first for the sale of butter short in weight and low in fat, the second against an eastern manufacturer for selling substandard citrate of magnesia. Two new divisions were created during the year, a unit for assay of vitamin claims in food products and for research in vitamin standardization, and a unit to handle the work connected with biologic products. These were reported in *THE JOURNAL*, August 17, page 522.

Further Development of the Social Medical Program

In the competition for votes at the general election, which is now proceeding, each party dilates on the benefits it is prepared to confer on the country if returned to power. One of these is extension of the public health service. In an election speech Sir Kingsley Wood, minister of health in the late government, said that development of the social services formed one of the most important parts of the government's election program. What was needed was a comprehensive plan for the development of the public services as a whole, with two main objects—protection of the community from unhealthy surroundings and complete provision for every individual of such personal services as might be needed at the various stages of life. In short, the policy was to provide decent conditions and the health to enjoy them. Considerable progress had been made toward the attainment of the first aim. The first essential of a healthy environment was a home. The national government had already a comprehensive housing policy, which was being carried out rapidly. It had made a direct attack on the two evils of bad housing—slums and overcrowding. Sixty-thousand slum houses had been pulled down and already 280,000 persons had exchanged the squalor of slum life for modern healthy homes.

MATERNITY AND CHILD WELFARE

Steady progress had been made with the provision of antepartum clinics, which increased from 1,101 in 1930 to 1,493 in 1934, and of hospital accommodations. This progress must be continued. But while the work had resulted in a gratifying reduction of infant mortality from 128 per thousand live births at the beginning of the century to 59 in 1934, there had been no reduction in the maternity mortality. The causes of this failure were not yet fully understood, and the government was giving unremitting attention to the problem. Notwithstanding the good work that was being done there were in many areas a gap in the health services and an urgent need for a salaried midwife service to secure for every woman who required it skilled care in childbirth. If returned to power, the government would introduce legislation for this purpose. Further provision was required for the needs of children under school age. In areas where the mothers could not give children the requisite care and attention, the government would encourage the provision of nursery schools in which good food, fresh air and skilled attention and training would give the youngest children a good start before elementary school days began. For the health of the school child elaborate provision was made in the school medical service, but in many parts of the country facilities for treatment, particularly dental treatment, were in need of expansion. These deficiencies would be remedied, and more remedial and preventive treatment in the form of orthopedic centers and open-air schools would be provided. At present there was no medical supervision between the time when a child left school and the age of 16, when he became eligible for health insurance. That gap would be filled. After children left school, health could be maintained only by systematic physical education, in which games and physical exercises played an important part. The government would promote a scheme of physical education covering all types of schools.

A Bone Setter Must Not Use the Title "Surgeon"

For fifteen years a bone setter had treated fractures, dislocations and disorders of bones and joints at Sheffield, Cardiff and later Paignton and other places in Devon and Cornwall, which he regularly visited. He put up a plate describing himself as

"manipulative surgeon" As he had no medical qualification, the Medical Defense Union wrote to him, pointing out that he was infringing the medical act in using the title "surgeon." He replied that he was not using the title surgeon and added "Prove that I am not a manipulative surgeon and I will remove the words from my plate." He was therefore summoned, but the court dismissed the charge that he was infringing the medical act. An appeal against this decision was made and was heard by the lord chief justice and two other judges. It was contended that the act contained an absolute prohibition against the use of the title "surgeon" by an unregistered person. For the respondent it was contended that he did not use the word "surgeon" by itself and that coupling it with the word "manipulative" was not unlawful and did not imply that he was registered under the act. The court reversed the previous judgment. The lord chief justice said "If a man was not a surgeon he must not call himself surgeon and the use of the adjective 'manipulative' did not alter the case. If the respondent desired to represent to the public that he was not a qualified surgeon many other descriptions were open to him, such as 'manipulative healer'."

District Nursing

An extensive charitable organization exists for "district nursing" (nursing the poor in their own homes). It owes its origin to William Rathbone, who in 1859 provided a nurse to work among the Liverpool poor. The Metropolitan and National Nursing Association was formed in 1875 by the Order of St. John of Jerusalem to train hospital nurses for district work. Subsequently county nursing associations were formed. In 1887 the work was consolidated and raised from the sphere of individual effort to that of a national institution. In 1926 it was calculated that, on a basis of one nurse for 10,000 of the population, nursing was provided for 75 per cent of the population. Subsequent experience showed that there is more work among an industrial population of 10,000 than one nurse can undertake. A survey of the district nursing in England and Wales, compiled by the Queen's Institute of District Nursing, shows that of the 39,864,184 population of England and Wales a nursing service is available for 38,206,867, or 96 and 87 per cent respectively in those countries. The increasing demand for domiciliary nursing indicates that an extension of the service may be expected. The income available for the service is about \$5,000,000 per annum and a nurse costs about \$1,150. In addition to the fund, money is collected in the form of gifts from patients and through provident payments.

The Care of Mental Defectives

Sir Laurence Brock, chairman of the Board of Control (which controls the administration of the lunacy laws) has stated in a public speech that mental defectives if uncared for, usually live in the worst conditions. There was a danger that, unless something was done, they would turn model cottages into slums. This had happened in some parts of the country. Of 300,000 mental defectives in this country, two thirds need not be segregated but should be allowed to live in the community. Here voluntary workers could help a great deal under experienced trained organizers. The colony system was the most economical method of dealing with the other third. Some people suggested that, instead of the patients being allowed to live in attractive villas, it would be cheaper to build barracks. Initial costs were bound to be high, but he was hopeful that the cost of maintenance would be further reduced. The aim was to give an atmosphere of village life. Many mental defectives were keenly alive to their surroundings. Seeing that they had been deprived of their liberty for the benefit of the community, it was only fair that they should live under happy, pleasant conditions. There was a strong case for sterilization although its advantages might be exaggerated. A better instructed public opinion was needed. It was far too common

for well intentioned people to encourage the marriage of defectives when a girl was expecting childbirth. There was a far better chance for the illegitimate child of mental defectives if reared in an institution than for the legitimate children of defectives, often reared in deplorable homes. There was no justification for the dismal articles in the press suggesting national deterioration. The problem was far too serious to lend itself to sensational treatment.

Congress on Gout

It is the custom of the leading thermal resorts in France to organize meetings every fall at which the ailments for which the individual resort is famous are discussed by leading medical men. The congress at Vittel this year was devoted to the various aspects of gout.

A paper on the pathogenesis of gout was read by Merklen and Wolf. Four elements must be considered (a) uricogenesis, (b) uricolysis, (c) hyperuricemia and (d) elimination of uric acid. Uric acid is the result of disintegration of nucleins. The role of the four nucleic acids, which give rise to the nucleins, seems to be that of a buffer in compensating the variations of the acidity or alkalinity of the nuclear medium. The majority of organ extracts furnish ferments ready to act on nucleic acids, so that the conversion of the latter into uric acid is a widespread process in the organism, that is, every tissue can give rise to uric acid. This is especially true of the liver.

As to uricolysis, nitrogenous waste is eliminated so far as albumins are concerned in the form of urea, and for nucleins, in the form of uric acid. The latter as found in the urine is of either endogenous or exogenous origin. One encounters some cases of gout without hyperuricemia, but this is not true for the majority. Hyperuricemia is found in conditions other than gout, such as during the pneumonic crisis and in leukemia. The kidney in gout has a certain almost pathognomonic impermeability or threshold for uric acid, which appears early and is quite elective. The clinical study of attacks of gout reveals the existence of a striking analogy to other acute crises, such as those of asthma. The grouping gout, asthma and eczema is not an uncommon clinical finding, in all of which there exists a condition of hypersensibility of the neurovegetative system. To sum up the pathogenesis of gout, there is hyperuricemia as the result of faulty elimination, humoral instability with an exaggerated tendency to precipitation of acute attacks of gout under the influence of cholesterinemia, certain neurovegetative factors and finally participation in the formation of tophi by histiocytes and reticulo-endothelial tissue.

Gout and allergy were discussed by Pasteur Vallery-Radot and Mauric. For years the sensibility of gouty individuals to certain foods has been known. The attacks of gout are not an anaphylactic manifestation, although a specific hypersensibility exists in some cases. Although certain authors regard the tophi as a form of tissue allergy, the authors believe this to be not proved. All together, the role of allergy in the etiology of gout is not demonstrable beyond all criticism.

Brodin and Grigaud spoke on the metabolism of uric acid in gout. Uric acid is the end product of nucleoproteins, with the purines as an intermediary stage. The uric acid may have its origin thus in the food (exogenous) or in the tissues (endogenous). Retention of uric acid (hyperuricemia) is the direct result and often the first sign of inadequate renal activity.

The role of the liver in gout was the subject of Noel Fiesinger's paper. One finds large livers the seat of a hypertrophic cirrhosis in gouty individuals. As the cirrhosis develops and is accompanied by signs of hepatic insufficiency, the gouty manifestations recede. Icterus in gout is rare and, if present, is due to other causes, but cholelithiasis is a frequent finding.

Fiessinger does not believe that such a biliary lithiasis is to be associated with a hypercholesterinemia, any more than the gouty tophi due to a hyperuricemia. He is of the opinion that the liver in gout allows nonmetabolized purines to remain in the circulation. Uric acid is an inert end product. The still undiscovered chemistry of gout lies in the metabolism of purines and xanthines. The entire body, and not the liver alone, plays a part in the metabolism of purines.

Loeper and Lemaire spoke on disturbances of nutritive exchanges in gout. The real cause of hyperuricemia is still unknown, that is, whether it is due to an excess of uric acid in food, abnormal formation in the tissues or inadequate elimination. One always finds a hypercholesterinemia, so that it is indispensable to make tests as to the existence of this condition, in the form of an intradermoreaction, a flocculation test and an estimation of the cholesterolytic power of the blood serum.

Guy Laroche maintained that biochemical studies are of great interest in gout but that it would be dangerous to base one's treatment on the results of laboratory research alone. Clinical experience should play the dominant part by (a) regulation of the digestive function, (b) giving the overworked liver a chance to recuperate, (c) stimulating elimination by the lungs, kidneys and skin, and, finally, (d) giving sedatives for the unstable neurovegetative system. A diet too rich in purines is not the sole underlying cause of gout, but a disturbance (endogenous) of nitrogen metabolism ending in excessive uric acid production or elimination is just as important. It is a fact based on clinical and biochemical observation that a meat diet is harmful and a vegetable diet beneficial in gout. Hence foods rich in purine or oxalates should be suppressed. The same is true of alcoholic beverages. Attention should be paid to general hygiene and to physical exercises. Although climate does not play an important part, it is advisable to avoid a sojourn at the seashore or in cold regions.

De Gennes discussed the atypical forms of gout. One sees less frequently now the classic localization in the joints of the toe, but, on the other hand, the atypical forms have become common. The polyarticular form may resemble an acute articular rheumatism but the age of the patient, the tendency to involve fewer joints, the resistance to salicylates and the almost specific action of colchicum make the diagnosis of gout easy. The pseudophlegmonous form is the most important of the atypical forms of gout. It may resemble a diffuse cellulitis at some distance from an articulation and may impress one, by its diffuse redness, edema and associated regional lymphadenitis, as being an acute suppuration. The phlebotic type is not difficult to diagnose except in cases in which there is no accompanying joint involvement. One of the most interesting of these atypical forms of gout is that in which the joint effusion and periarthritic edema are not accompanied by acute symptoms and thus resembles a tuberculous arthritis. The differential diagnosis can be readily made by the prompt response to colchicum in gouty arthritis. It is easy in these atypical forms to make a diagnosis of gout if tophi are present, but these are lacking in the majority. The blood examinations for excess of uric acid or cholesterol is not to be depended on in these atypical forms of gout. The rapid development of the muscle and articular lesions, the absence of an atrium of infection, the good general condition of the patient and the quick response to colchicum constitute the best arguments in favor of an atypical form of gout. De Gennes does not believe that there is such a clinical entity as visceral gout. Such symptoms are due either to renal or cardiac insufficiency or to hypertension.

Perrin and Abel spoke on the medical treatment of gout. The principal drugs to relieve the symptoms are the derivatives of salicylic acid, especially sodium salicylate, then the cinchophenic derivatives whose base is quinoline, and colchicum. The latter may be regarded as an almost specific drug in acute gout but it must be employed with much discretion and only when cardio-

renal complications do not exist. In chronic gout, colchicum should be discarded in favor of the salicylate and cinchophenic derivatives. Other drugs that act as uric acid solvents are also indicated. Tonics (iron, arsenic) also must be given from time to time. There has been much discussion of alternating alkali and acid treatment. The results have been good, but one has not yet been able to explain them on a scientific basis.

Lian and Gilbert-Dreyfus took up the cardiovascular system in gout. Symptoms of this character are relatively rare in gout and the latter plays an insignificant part in the etiology of atherosclerosis, hypertension and angina pectoris.

Further Developments at the Universities

Reference has been made in several letters to the influence exerted by the new political régime on the universities, university instruction, the instructional corps and the student bodies. Further developments have taken place of late.

GENERAL AIMS OF THE UNIVERSITY

At the dedication of the new Cologne university, a few months ago, Rust, the minister of public instruction, expressed his views on the general aims of the university. He said: "Our science and our research have their fundamental origins in the hearts and the minds of our people. Consequently it is clear that much that has hitherto been surrounded by a halo of unquestioned acceptance is now declining and will soon sink into oblivion." He brought out further that the realms of the spirit dominating our intellectual life are undergoing a gradual metamorphosis. Even the erudite professors would have to unlearn much and learn much that is new. Professor von Haberer, surgeon and rector of the University of Cologne, emphasized on this occasion "how infinitely difficult the metamorphosis of the German people in the spirit of the new ideas was going to be. The establishment of the national-socialist German folk culture, planned so majestically over a period of many centuries, can be brought about only at the cost of untold labor, and will require, on the one hand, great caution and discernment and, on the other hand, a keen insight into the future." He said that as rector (president) he would administer the affairs of the university in the spirit of the new Germany. The spirit to which he gave expression was that of a university of, for and by the German people. It was in line with this spirit when, in July, Dr. Wagner, the federal fuhrer of the physicians, emphasized that "the new trend of university policies is controlled by the national-socialist party and the way that the party plans to go is so clear that no further discussion is needed." The remark of Dr. Ley, the fuhrer of the German labor front, concerning "the unchecked devotion to the god of science" is also deserving of mention.

On the other hand, the approval by the university instructors of all these decrees and newer trends is not so universal or so complete as may appear. The views expressed at the festivities in commemoration of the founding of the University of Munich caused dissatisfaction in government and party circles. To express it tersely, the spirit of the instructional corps was disapproved. The traditional celebration held in the university "aula" drew only a small representation of the instructors (less than 25 per cent), who were supposed to attend in a body and sit with the members of the national-socialist student league. The lack of participation in the prize essays and the mediocre quality of the essays presented at the commemorative ceremonies have been taken as evidence of inadequate cooperation between the instructors and the students. In response to a letter from the Bavarian "ministerpräsident" to the rector (president) of the University of Munich, which gave expression to these criticisms, the latter answered that he wholly

disapproved the attitude taken by the university instructors at the commemorative exercises

The federal minister of public instruction has issued instructions with a view to making the administration of the universities more uniform. The university personnel is divided into the instructional corps and the student body. The instructional corps consists of the teaching force of the university, together with assistants. The head of the university is the rector, who is subordinate to the minister and immediately responsible to him and to him alone (formerly the rector of a German university was chosen by his colleagues, or fellow instructors, and was *primus inter pares* for the period of one year). The pro-rector, or vice president, and the deans of the faculties are appointed by the minister from a list of candidates proposed by the rector. The "studentenschaft," or official student body, comprises students of German origin whose mother tongue is German, irrespective of the country to which they owe allegiance. The leader of the official student body of a university is appointed by the minister of public instruction following suggestions obtained from the rector and the "gaufuehrer" (county chairman) of the national-socialist student league, and he is under the authority of the minister. The university "senate" serves the rector now merely in an advisory capacity. This covers the most essential provisions of the new order at present in force at German universities. Thus, the official student body (the "studentenschaft") has acquired equal rights with the instructional corps. The "senate" was formerly the chief authoritative body of the university, but now it has only advisory functions. It is apparent, therefore, that the rigid application of the "fuehrer" principle has had a marked leveling effect on all the university personnel, including both instructors and students. The deans are now the fuehrer of their respective faculties.

A doctor's degree in a new field can now be secured. The University of Hamburg is conferring a doctor's degree for advanced study in "sportwissenschaft," or the scientific aspects of participation in the various sports and the supervision by athletic directors of the devotees of sport activities. Athletic directors and instructors in the various sports (coaches) may now present a scientific thesis in the field of physical education. In the instructional corps a complete reorganization has taken place. All members of the national-socialist party within the instructional corps of the several universities, including the assistants, have been organized into a national-socialist league of university instructors, which, in combination with the national-socialist league of students, constitutes the official party organization at the universities. The league of the instructors and the league of the students are expected to work together in the closest manner. The local fuehrer of the league of instructors and likewise the fuehrer of the league of students are under the authority of the so-called party service centers in matters of discipline.

Likewise in the scientific activities of the university certain controls have been introduced. Among other things, the minister of public instruction has decreed that all persons under his jurisdiction (that is, all professors, instructors and students) who are requested to deliver lectures in a foreign country or who wish to attend international congresses or similar conventions, to be held in foreign countries, must secure his approval. The purpose of these restrictions, it is officially stated, is "to make sure that representatives of German science who are heard in foreign countries shall be of the type that will best conserve the cultural and political interests of the reich." In many cases the foreign office and/or official sources of information in foreign countries will be consulted before a decision is reached. The minister of public instruction likewise demands that full-time university instructors shall not assume any secondary duties or take on themselves any secondary tasks without first securing his approval of such undertakings. Head physicians

and assistants in clinics may serve private clients only after securing his consent. It is thought that, in many cities in which universities are placed, local physicians will appreciate this attempt to remedy a long existing evil.

In a previous letter (THE JOURNAL, April 6, p 1259) reference was made to the new regulations governing the "entpflichtung" of professors, or debarring them from holding the particular courses of lectures that are naturally incident to the chair that they hold. Now the limitation of the rights of professors who have been "relieved of their official duties" has been put on a different basis. Formerly, such professors had the privilege of continuing their lectures as free lances, or at least of delivering lectures on some branch of their special field, in case they had been compelled to turn over to their successor their central course of lectures. Many of the professors thus "relieved of their official duties" made use of this privilege, and their lectures were often gladly attended by the students as a supplement to the usual courses. Now the minister of public instruction has ordered that the professors thus relieved of their official duties shall not have the right to continue their activities as lecturers, even though their new courses of lectures do not conflict with the courses of their successor. Consent to continue lecturing will be granted only "in case the petitioner (that is, the professor relieved of his duties) furnishes the assurance that he will endeavor to fit in with the new spirit that now prevails in the German universities, and that his political attitude will not endanger the educational work that the national-socialist party has planned for the academic youth." Furthermore, the lectures of professors who have been "relieved of their official duties" must not interfere in any way with the central courses of lectures that are to be taken over by the new incumbent of the chair, whether his appointment is merely provisional or definitive, since to him, as the occupant of the chair, must be reserved the right to map out his courses as he deems best.

The Crusade Against Cancer

The ministry of the interior and the ministry of public instruction have agreed to cooperate with the city of Berlin in carrying on a crusade against cancer. Their common endeavors envisage the support of all practical and scientific movements and collective action with respect to all organized efforts to suppress all forms of cancer, in providing continuation courses for physicians, and in the better training of the oncoming generation of physicians. The execution of the extensive plan is based on large-scale arrangements in the largest Berlin hospital, the Rudolf Virchow-Krankenhaus, whose clinical departments and modern roentgenologic institute furnish especially favorable conditions, which can be still further amplified as need arises. Within this hospital a large "general institute for the combating of cancer" has been created, in which treatment, research and instruction will go hand in hand. The university institute for cancer research, established many years ago at the Charite Hospital in Berlin, has consented to cooperate in this collective movement, although the two institutes will preserve their complete independence. The whole movement as so organized will keep in close touch with the federal commission for the combating of cancer, of which Professor Borst of Munich is chairman. The mayor of Berlin and the medical faculty of the University of Berlin are members of the honorary committee of the institute.

The creation of this institute is not designed to effect a concentration of cancer treatment, on the contrary, every clinic and every hospital, within the range of their capacities and equipment, will continue to participate in scientific research and in treatment. In the new institute the clinical point of view will be in the ascendancy, hence Professor Sauerbruch has been chosen director. The new institute has already begun to function, and many cancerous persons are being brought in.

Annual Meeting of British Medical Association
at Melbourne

As stated in a previous letter (*THE JOURNAL*, November 16, page 1620), the one hundred and third annual meeting of the British Medical Association opened September 9 in Melbourne.

THYROTOXICOSIS

The most interesting scientific session, a joint meeting of the sections of medicine and surgery and one that was attended by 800 members, was the discussion on thyrotoxicosis. Lord Horder considered that the thyroid hyperplasia associated with exophthalmic goiter was not a primary but a secondary phenomenon. The *causa causans* remained obscure, although partial thyroidectomy might interrupt a vicious circle, just as a splenectomy could in splenic anemia, but did not get rid of the cause of the trouble. The existence of a diathesis in the disease was generally accepted. Of the predisposing factors little was known—sex, certain collateral familial conditions and an autonomic imbalance. Of exciting causes there were the sex epochs, psychic trauma and focal sepsis. The evidence regarding associated endocrine defects was entirely unconvincing. The recognition of the diathesis called for preventive treatment; this was a thankless task. The simple life was necessary, and for those patients who accepted the control and cooperation of the medical attendant there was a good promise of stabilization. If the symptoms persisted in spite of controlling the patient's routine of life, and whenever the full syndrome had developed, absolute rest in bed for at least three months was needed. There were no specific drugs, but belladonna, among others, had been found useful. The operation of thyroidectomy should be undertaken if the patient failed to respond to six months' careful medical treatment, in cases that relapsed, and when associated with auricular fibrillation or congestive heart failure.

Sir Thomas Dunhill drew attention to the steady advance of the stage at which operation was now performed. Roentgen therapy had its place in the treatment of the early stages, and in young people. In severe cases and older patients, the results from surgery were better. He preferred the one stage operation. Auricular fibrillation was the commonest complication. He found that 84 per cent of his series regained their normal rhythm after operation, and 6.5 per cent had died. The next common complication was glycosuria, which was sometimes insulin resistant. Mental disorder was next on the list, and the difficulty of this complication arising after the operation was mentioned. Emaciation was a factor that would always keep the general death rate of the operation up to 3 per cent.

Prof C E. Hercus of New Zealand drew attention to the thyroid and hydatid muddledness of the dominion physicians. New Zealand had the highest relative death rate from thyrotoxicosis in the world—three times as great as Great Britain. He said that endemic goiter and thyrotoxicosis went together. Nearly all cases of goiter exhibited some degree of toxicity, therefore the division into primary and secondary had no pathologic basis.

Dr A W Holmes of a Court of Sydney urged the necessity of giving iodine for a fortnight before operation. The patient was then at the height of a remission.

Sir Carrick Robertson of New Zealand was convinced that the toxicity of adenomatous goiter was increasing. His practice was to remove from four fifths to five sixths of the gland in one stage if possible. The preliminary ligation of the superior thyroid artery had not in his experience, improved the patient. His mortality rate was 0.9 per cent. Two of these had "woody" thyroids and four suffered from the type described by Lahey as "apathetic" hyperthyroidism.

Dr Turnbull of Melbourne had found that the pulse rate during sleep was helpful in management. If below 75 per minute, operation could be safely postponed in young subjects. Older people could not safely be left without operation, as cardiac failure and auricular fibrillation might come on quickly. He had been disappointed in the value of the estimation of the basal metabolic rate. It was unreliable in the young and not indicative in the old. He had found iodine of value as a diagnostic agent, in thyrotoxic cases an exacerbation occurred fourteen days after stopping the drug.

Dr Alan Newton of Melbourne astounded the meeting by stating that he had operated on 512 patients—a number just sufficient to convince him that he knew nothing about the disease. His mortality was 0.4 per cent in his private practice and 3 per cent in the public hospital. He considered that the difference was due to the frequent changing of the nurses in the latter. Roentgen therapy had its best scope when regeneration occurred after operation.

Dr S F Hansman of Sydney described the negative phosphorus and calcium balance that had been found to be associated with hyperthyroidism, possibly due to an associated hyperparathyroidism. The negative balance was not influenced by rest and iodine, but roentgen therapy had restored it to normal.

HYDATID DISEASE

Although, in Australia, knowledge of hydatid disease was second to none as there was an unrivaled opportunity for its study, observers here had still much scope for further investigation.

Prof H R Dew of Sydney, who is possibly the greatest authority on hydatid disease in the world today, opened a discussion on the advances in knowledge of this disease during the twentieth century. The highest incidence was in the last decade of the nineteenth century. The Royal Australasian College of Surgeons had established a registry of hydatid disease, which should provide valuable statistical material in the future. Caution was expressed against the injudicious use of solution of formaldehyde for injecting the cyst for the purpose of sterilizing its contents. The optimal concentration of solution of formaldehyde in the cyst was 15 per cent.

Prof D W Carmalt Jones of New Zealand discussed the life history of the *Taenia echinococcus*. He pointed out that a primary cyst acted as a benign tumor, producing only pressure effects, if any. It obtained its nourishment from the host, the walls being pervious, and in the early stages enough material often passed out of the cyst to sensitize the host's tissues and give a positive skin reaction. The fibrous adventitia, derived from the host, might become so thick as to starve the cyst, which then died, and the adventitia might become calcified. The record primary cyst contained 22 pints (11 liters) of fluid. If a cyst wall was injured, the life of the parasite might be preserved by the development of daughter cysts of similar structure to that of the primary cyst, probably by cystic transformation of the scolices. Such a cyst was much like a malignant tumor for the reason that it might produce untoward effects as a result of rupture. In addition to pressure effects the two grave risks of hydatid disease were suppuration and anaphylaxis.

Dr Keith D Fairley of Melbourne discussed the laboratory diagnosis of hydatid disease. Eosinophilia was useful only as suggesting investigation by more specific tests. The precipitin test closely paralleled in its results the complement fixation test, but minor reactions were difficult to interpret. The complement fixation test was specific, but failure to react was of no value in excluding hydatid disease. The results were positive in only 54 per cent of preoperative tests with primary or recurrent or residual cysts. Within two or three months after operation the serum might fail to react to the test. The chief value of the test was in the diagnosis of primary suppurating or ruptured cysts and of residual recurrences. Since some

patients reacted with this test but not with the intradermal test, both should be employed in the preoperative diagnosis of primary cysts. In regard to the intradermal test, the delayed reaction should always be looked for, as occasionally a positive result might appear when the immediate reaction failed to develop. The immediate reaction was of great value in the preoperative diagnosis of primary cysts but was of no help in the diagnosis of recurrent or residual cysts. Repeated injections of the same field might sensitize the skin in this locality and lead to fallacious results. In primary preoperative cases a positive result was obtained in about 75 per cent of those with uncomplicated or degenerating and degenerated cysts. After operation the reaction was almost invariably positive and usually remained so for many years. Results showed that after the primary operation a negative result might suggest but did not prove cure, while a positive result was of no significance in the diagnosis of recurrent cysts. The high incidence of latent cysts (16 per cent) discovered at necropsy necessitated post-mortem proof of the absence of hydatid infestation when an apparently fallacious positive result was obtained. One of the chief values of the test was in excluding hydatid infestation. In about 2,000 cases a negative response had correctly indicated the absence of hydatid disease in 95 per cent.

CARCINOMA OF THE COLON

The necessity for a defunctioned and a debacterialized colon before attempting an anastomosis, and the unsatisfactory results of a cecostomy were stressed by Dr H B Devine of Melbourne in discussing carcinoma of the colon in the section of surgery. If the operative mortality rate could be lowered the disease should be eminently curable by surgery, as it did not metastasize early. The patient with carcinoma of the distal part of the colon generally came to the surgeon in the middle stage of his disease. (a) chronically poisoned (metabolically) from the toxic effect of a slowly growing carcinoma, (b) chronically poisoned from the prolonged absorption of the toxic products resulting from chronic intestinal obstruction, (c) with colonic tissue devitalized from the general poisoned condition and also from the local effect of the chronic intestinal obstruction, (d) with highly pathogenic germ content of the colon. Dr Devine's method of operating for carcinoma of the distal part of the colon was based on the principle that, if a segment of an animal's bowel was experimentally isolated and thus deprived of its function, its bacterial content would slowly disappear. He therefore first of all disconnected the proximal from the distal part of the colon. This disconnection was made at the transverse colon if it was mobile enough, otherwise it was made at the hepatic flexure. The cut ends of the bowel were inserted into small separate openings in the abdominal wall. The distal part of the colon was thus completely "defunctioned" and time became a factor in its "debacterIALIZATION". Subsequently the growth was resected.

Dr Victor Hurley of Melbourne said that 50 per cent of tumors were inoperable when diagnosed. There were no characteristic symptoms in the early stages, and one should be guided to the diagnosis by the association of trivial features. Upper abdominal lesions were often simulated. Examination for occult blood should always be done. Patients were often well nourished, and anemia was a late feature. Sigmoidoscopy should be done with no anesthetic and without any preparation. An opaque meal might sometimes precipitate complete obstruction.

PROSTATECTOMY

The importance of eradicating the whole of the diseased portion of the gland was stressed by Dr A Clifford Morson of England. Throughout the discussion the Harris method was regarded as a standard technic. Recurrence of prostatic enlargement was a demonstration of failure on the part of the surgeon who had performed the operation. By the Freyer and Thomson Walker methods the prostatic cavity after enucleation

was left bare of mucous membrane and no attempt was made to unite the bladder to the torn end of the urethra. Eventually this union occurred by what might be termed secondary intention. Harris, on the other hand, claimed that he obtained union by first intention. The difference between healing by secondary and primary union was in the amount of fibrous tissue that formed. With the introduction of the Thomson-Walker technic, stone formation had become a rare complication, but postoperative urethral obstruction still occurred.

Turning to the Harris technic, Dr Morson said that Harris reconstructed the internal meatus. This insured more rapid healing and, by preventing urine from coming into contact with tissues uncovered by mucous membrane, reduced sepsis. The postprostatic pouch was obliterated by drawing down the base of the bladder to the level of the bed of the prostate with the aid of catgut sutures. Cysto-urethroscopy during the convalescent period showed that the new internal meatus was on the same plane as the interureteral bar. There was thus no opportunity for urine to stagnate in the region of the ureteral orifices. Because of successful hemostasis it was possible to close the bladder without suprapubic drainage. In about 50 per cent of Dr Morson's cases there was no leakage of urine through the abdominal wall.

In the last section of his paper Dr Morson discussed the avoidance of certain complications. He referred among other subjects to the safeguarding of the seminal vesicles. He attempted to sterilize these as well as the urethra, before enucleation was commenced, by irrigation through the proximal end of the divided vas deferens, with a 1 in 60 solution of phenol (carbolic acid).

Dr G H Burnell of Adelaide had found blood urea estimations of little assistance and frequently found remarkable variations in the results of the urea concentration test. The lack of correlation between the results of these two tests had led him to discontinue blood urea estimations. He relied on the indigo carmine test, using Thomas's method. Dr Burnell always ligated the vas and used a subcutaneous catgut suture. The Harris technic was suitable for every surgeon.

Dr Richard Harris of Sydney discussed technic. The first incision in a two-stage operation was always a short transverse one 2 inches above the symphysis. He always used the bimanual intra-urethral method of enucleation. Visualization of the prostatic cavity with Harris's retractor was practically perfect. In the process of retrigonization the whole thickness of the trigon was pulled down. Primary closure was not an essential part of the operation, but a nicety of technic. Five hundred and forty-seven patients had now been operated on by S H Harris, and the mortality was still 27 per cent. In the estimation of renal function he relied entirely on the indigo carmine test.

SURGERY OF THE PANCREAS

The desirability of avoiding immediate operation for acute pancreatitis and the value of the urinary diastase test in diagnosis were the chief points made in a discussion on the surgery of the pancreas, in the section of surgery, opened by Dr Harold Upcott of Hull. In regard to acute pancreatitis, he said that certain facts emerged from the experiments carried out to explain the pathology. 1 Acute edema of the pancreas followed the injection of bile into the pancreatic duct. 2 If the injection was combined with damage to the acinous cells as by injection under pressure or by some other means, the ferments were activated and acute necrosis occurred. In a certain proportion of cases the terminal bile and pancreatic ducts were so disposed that an obstruction of the common orifice would allow the entry of bile into the pancreatic duct. It was usual to recognize three types of acute pancreatitis: hemorrhagic, gangrenous and suppurative. There was also a milder inflammation, which had been described as acute pancreatic edema. Passing to consideration of the chronic dis-

orders, the principal difficulty in diagnosis, he thought, was the distinction between chronic pancreatitis and cancer of the pancreas. Even at operation it was not always easy to decide. The surgical treatment of chronic pancreatitis was essentially drainage of the biliary system, either by establishing a temporary external fistula from the gallbladder or common duct or by diverting the bile from the gallbladder into the stomach or the duodenum. He classified pancreatic cysts into four groups: (1) retention or canalicular cysts, (2) neoplastic cysts, (3) pseudocysts, (4) parasitic cysts. Malignant disease of the pancreas was almost always carcinoma. If the diagnosis was confirmed at operation, the simplest method of diverting the bile should be practiced. Dr Upcott concluded by referring to disturbances resulting from alteration in the internal secretion. In regard to increased secretion, he described the symptoms of the hypoglycemic state and pointed out that, if all the other causes of the hypoglycemic state could be reasonably dismissed, it appeared justifiable to advise exploration of the pancreas, for in no other way could the presence of an adenoma of the cells of Langerhans be determined.

OBESITY

Dealing with the endocrine aspect, Sir James Purves Stewart of London in the section of medicine classified obesity into 1 Pineal obesity, which occurred in patients with pineal tumor, but in all such instances pressure occurred on adjacent organs or produced internal hydrocephalus. 2 Hyperinsulinism, such persons were frequently fat rather than thin. 3 Genital eunuchism in the male and menopausal obesity in the female. 4 Adrenal, especially in nondestructive tumors of the gland in women and associated with involution of the uterus and adnexa. 5 Subthyroid, to be diagnosed only when the classic features of obesity were found. 6 Subpituitary, constituting the commonest form of all, and due to a deficiency of the secretion of the basophil cells, which were found in the anterior lobe of the gland and sometimes in the posterior lobe. Obesity with dwarfism occurred when the deficiency also affected the acidophil cells of the anterior lobe. The Fröhlich syndrome was frequently seen in children with sellar and suprasellar tumors showing characteristic pressure syndromes. Grave doubts existed as to whether this obesity was purely endocrine in origin. It was probably rather neuro-endocrine, as, for example, in the obesity of internal hydrocephalus causing compression of the infundibular stalk. 7 The Cushing syndrome, due to suprapituitarism of the basophil cells of the anterior pituitary, which was not entirely a secretory disorder. It was frequently associated with the characteristic sign of hyperadrenalism, hyperparathyroidism and ovarian deficiency.

Dr J H Anderson of Ruthin Castle warned against reduction of diet in true hypothyroidism, as the patients stood it badly. In genital obesity, diet, exercise and thyroid gave the best results, and the same three measures were necessary in pituitary obesity, with the addition of whole gland pituitary extract. Drugs especially thyroid, were controlled by estimating the basal metabolic rate and the tolerance to sugar, and by keeping a watch on the pulse rate.

Prof C G Lambie of Sydney took an accountant's view of the situation. On the debit side of an energy balance table there was expenditure of calories: (a) for basal metabolism, which consumed by far the largest amount of heat, (b) by exercise, which required relatively few calories, and (c) specific dynamic action, the technical measurement of which in man was difficult. The last mentioned represented the smallest fraction and was mostly decreased in obesity. Food constituted the credit side of the balance and was the most important single variable factor. If the energy intake was less than the energy consumption there would be a loss of energy building tissue, otherwise the laws of conservation of energy and mass would be contravened. This was the basis of all rational treatment.

The important problem in obesity was what happened to food taken in excess of caloric requirements. Five possibilities arose: any of which might be responsible for the development of obesity: limitation of absorption, elimination, increased mechanical work, combustion (luxus consumption) and storage. Energy consumption was determined not by a supply of energy but by the margin of tissues, any excess of intake over requirement being stored chiefly as fat. This being true any continued excess, even if slight, of intake over requirement would eventually result in obesity. In general, body weight might nevertheless remain remarkably constant. Big eaters who led a sedentary life free from worry and with plenty of sleep failed to increase in weight, while others of similar age, sex and height who took only a fraction of the amount of food and led an active life became fatter. The first group were said to have a high luxus consumption. It made no difference from the point of view of energy whether the luxus consumption was high from increased burning of food or from entry storage. Diminished burning of food was frequently associated with a low basal metabolic rate, but increased storage occurred in the majority with a normal rate of metabolism. This storage was apparently due to increased conservation of carbohydrate and of the fat. Glycogen synthesis was apparently linked with this process while practically all forms of obesity were associated with an increased glycogen formation and not a mere accumulation, as occurred in von Gierke's description. This conception brought endocrine and nervous obesity into line with nutritional obesity. Endocrine obesity was roughly divisible into two groups: one with a high sugar tolerance and the other with a low sugar tolerance.

THE DIFFERENTIAL DIAGNOSIS AND TREATMENT OF SEVERE ANEMIA

As a working classification, Dr J C Matthews of Downton, England, adopted 1 Pernicious anemia. 2 Idiopathic hypochromic anemia. 3 Other deficiency anemias, for example, scurvy, myxedema. 4 Anemias characterized by hemolysis—acholuric jaundice, anemias due to chemical poisons, and so on. 5 Anemias secondary to (a) malignant disease, especially of the alimentary tract, (b) infections, (c) hemorrhage, acute and chronic. 6 Aplastic anemia. 7 Splenic anemia.

Dr Gunaratnam Cooke of Ceylon said that the chief anemias in his country were associated with hookworm infestation, in the course of which the blood picture sometimes changed from the secondary to the primary type. He had found combined treatment with liver and iron to be valuable. He stated that the complex terminology of the modern hematologist was most confusing to his countrymen, and he himself was content to call pernicious anemia 'large red cell anemia'.

DIABETIC GANGRENE

That disordered fat metabolism associated with an excess of blood cholesterol was the most important factor in the causation of diabetic arteriosclerosis was the contention of Dr A. Clarke Begg of Swansea, England. Diabetic gangrene was due to arteriosclerosis, increased susceptibility to sepsis, and diabetic neuritis. Amputation was the best course in wet spreading gangrene but conservative measures were indicated in dry gangrene. In the borderline case a good general rule was to abandon conservative treatment after four weeks if improvement did not manifest itself. Prophylaxis against gangrene was of the greatest importance.

Other speakers stressed the necessity for weak alcoholic antiseptics, including 2 per cent iodine. As a means of estimating the degree of arterial obstruction, the Pachon oscillometer was recommended.

FAMILIAL ACHOLURIC JAUNDICE

Once the diagnosis was made, splenectomy should not be long delayed, on account of the danger of fatal hemolytic crises, and the operative difficulties in older subjects.

Dr S O Cowen presented the histories of thirty-three patients, of whom seventeen were in one "family." Twenty of the thirty-three had been treated by splenectomy with no deaths. Ulceration of the legs, a common complication, had not recurred after operation.

GALLOP RHYTHM

It is important to distinguish between presystolic and protodiastolic gallop, since the former is a sign of grave significance and the latter is compatible with perfect health. Dr Crichton Bramwell of Manchester stated that protodiastolic gallop was due to accentuation of the physiologic third heart sound. It could be distinguished from presystolic gallop by the absence of any associated palpable impulse and by the unequal spacing of the sound. An accentuated third heart sound was generally audible in mitral stenosis, but presystolic gallop never developed in patients with this lesion, probably because auricular fibrillation intervened first. To appreciate gallop rhythm best, direct auscultation of the chest wall without a stethoscope allowed the double impulse to be appreciated as well as the double sound. The impulse itself was felt just to the left of the xiphisternum.

CESAREAN SECTION

In no uncertain terms, Dr J Bright Banister of London decried the modern popularity of the operation of cesarean section. The best mortality rate was 58 per cent. In his series of 3,846 cases the rate was 66 per cent. As the gross maternal mortality rate for England and Wales was 0.45 per cent, the operation had a considerably increased mortality. Dr Banister expressed the profound conviction that the operation was performed with undue frequency because of the tendency to regard obstetric problems from a surgical point of view. "Let the baby out," said the surgically wise but obstetrically foolish. Such counsel implied a contempt for nature, with its painful but safe technic. In alleged cases of pelvic disproportion section was performed without enlisting the aid of nature at all, or only after a mock trial of natural methods and in apparent ignorance of the fundamental facts of the mechanisms of labor. A second factor making for the undue increase in the number of cesarean sections was the inability of some obstetricians, deficient in practical training, to diagnose by examination the cause of delay in labor.

Prof J B Dawson of Dunedin crossed swords with Dr Banister and drew attention to the obvious fallacy in his statistical statement. Professor Dawson considered that the danger in British countries today was not that too many sections were being done but that too many were being done too late. The disasters did not follow prompt decisive action but operations performed after long delay, begotten by hesitation out of hope, a delay that added a terrific risk to subsequent operations.

Dr W Ivon Hayes of Melbourne quoted the cesarean incidence at the Women's Hospital as 0.8 per cent, with a mortality of 6 per cent. These figures covered fifteen years and a total of 43,727 deliveries. The highest death rates were in eclampsia (21 per cent) and accidental hemorrhage (21 per cent). It was considered that the indications were confined to (1) any degree of placenta praevia in a primipara not in labor, (2) any central placenta praevia, (3) any degree of placenta praevia when the child was a "good risk" and specially desired, and (4) gross disproportion. Fatalities tended to occur in the patients operated on late in labor. Lower segment cesarean section had so many advantages that it should become the regular method of abdominal delivery among obstetric surgeons. Hysterectomy was indicated when the patient showed signs of definite infection and when the membranes had been ruptured a considerable time, or when there had been a history of repeated examinations or repeated attempts at delivery.

BELGIUM

(From Our Regular Correspondent)

Sept. 21, 1935.

The Health Record Book

The Fédération médicale belge created recently the health record book, with the endorsement of the Conseil supérieur d'hygiène publique. This record book, designed for distribution by the physician in all the families, is well gotten up and will centralize all the information concerning the state of health of each member of the family. The creation of a health record book is the most practicable and the most effective method of promoting preventive medicine. The family physician, medical specialists, the army medical corps and certain other official services will have access to the health record book, which will be edited in such a manner that the uninitiated will be unable to understand the recorded diagnoses. This last point is of great importance, for in this manner professional secrecy will be safeguarded. Twenty-five years ago the use of the health record book was recommended in France, but with the difference that any one was able, by inspection of the book, to learn the state of health of the owner. It is to be hoped that many physicians and organizations of social medicine will support this innovation of the Fédération médicale belge, which, as time goes on, will become of ever increasing value.

The Medical Profession in Belgium

The economic crisis is still felt by the physicians of Belgium, particularly in certain large centers. The Belgian universities are nevertheless creating many new physicians every year. The question has been raised as to how this mounting flood can be checked. Various methods have been proposed, notably the creation of an entrance examination at the universities and the introduction of more rigorous term and final examinations.

The plethora of physicians is the cause for the excessive reductions in the medical tariffs, which leads to the remark that, in present-day society, the physician does not occupy the place to which he is entitled by reason of his extensive studies and the services that he renders humanity. The pharmacists and the nurses in exceeding their rights, the numerous societies of a prophylactic character, the provincial and communal hospitals and clinics, the mutual aid societies by their exploitations, the law pertaining to industrial accidents, and the inroads of charlatanism, bear a large share of responsibility for the prevailing conditions among the physicians.

The Fédération médicale belge has sought means of remedying this state of affairs. It has recommended as indispensable a closer union of all physicians and the creation of a sort of corporation with its code of ethics and its regulations, in order to combat all the trends that have a tendency to lessen the prestige of the medical profession. The federation has now become more insistent and demands the immediate creation of an "order," or ethical council, of physicians, it recommends, with regard to industrial accidents, the organization of a service of nation-wide scope, which would be placed at the disposal of the insurance companies, it has succeeded in getting the mutual aid societies to accept the principle of control of the medical features of the mutual aid societies by the medical syndicates, finally, a health insurance society is about to be organized. The Fédération médicale belge has the firm conviction that, if only the physicians will remain united, a better future is assured.

The Industrial Medical Service

After the close of the World War, the industrial medical service was reorganized on the following bases:

1 The industrial medical service is entirely distinct from the inspection of labor properly so called, and its jurisdiction extends to all places where workmen are engaged. As regards the 'right to visit,' the authority of the medical inspectors of labor

is absolute. They are subject only to the instructions furnished by the chief of the medical inspection service.

2 The duties of the industrial medical service have been interpreted as follows (a) to organize the protection of pregnant women and nurses gainfully employed, (b) to assure the sanitary safety of apprentices and to collaborate in their proper professional organization, (c) to study the physiology and the pathology of labor, (d) to bring the knowledge of its agents in special fields to the aid of all organizations dealing with social insurance, (e) to propagate the most useful ideas of professional prophylaxis, and (f) to control the enforcement of regulations of a medical nature.

At present the medical inspectors of labor, to the number of ten, carry out themselves the necessary inspection. To these should be added a woman inspector who is a graduate in medicine, and an inspector who is a doctor of science, for the inspection of laboratories.

To watch over the laws for the protection of the health of industrial workers, and the regulations of professional hygiene, in their applications, their enforcement, their amplifications and their possible improvement—that is, to sum up, the proper domain of industrial inspection.

In the performance of their duties, the inspectors have the right (1) to enter by day or by night the establishments under their supervision, (2) to issue, on the basis of their inspections, official reports receivable in courts of justice until proof of the contrary has been submitted, and (3) to propose to local authorities the closing of a plant by reason of manifest unhygienic conditions.

By reason of a vast collection of objective documents on the subject in hand, the industrial inspectors can now count on the aid of legislators in enforcing respect for the fundamental principles of industrial protection. In this connection a list of royal and ministerial decrees looking toward the health of workers and the hygienic aspects of wage scales has been promulgated.

Although the officers of the industrial medical service have a definite mission to perform and have not available as large a staff of investigators as they might desire, they nevertheless find opportunity to conduct special medical researches on saturnism, hydrargyrisms, anthrax, ancylostomiasis and kindred subjects.

An Ovation to the Surgeon Albin Lambotte

Special ceremonies in honor of the surgeon Albin Lambotte, whose work in the field of osteosynthesis is well known, were held recently in Antwerp. Most of the Belgian surgeons and several foreign surgeons came on this occasion to express to Lambotte their admiration. The first feature of the occasion was the formal reception of Dr Lambotte, in the beautiful surroundings of the Hotel de Ville at Antwerp, by the board of aldermen and the burgomaster Huysmans, who expressed to him the gratitude of the city for the eminent services rendered to the wounded and the sick and for the luster that his works had brought to his city.

In the afternoon an academic session was held at the Université coloniale, at which W. Franch, secretary of state, presided. Professor Hustin of Brussels eulogized the work of Dr Lambotte, following which Professor Sauerbruch of Berlin gave an address on the history of bone surgery, while Professor Leriche of Strasbourg outlined the future of bone surgery. In conclusion, the decoration of Commander of the Order of Leopold was conferred on Dr Lambotte.

In the evening the University of Brussels, at which institution Lambotte formerly studied and of which he is doctor honoris causa, gave him a banquet, following which the secretary of state, the president of the university and representatives of the Société nationale de chirurgie de Paris, the Société des chirurgiens de Paris, and the Société belge de chirurgie de Paris, presented their felicitations to the eminent surgeon.

Marriages

RAYMOND O. FRANKOW, West Bend, Wis., to Miss Elinor Turkish of Stevens Point in Fond du Lac, September 3.

GEORGE M. GREEN, Daytona Beach, Fla., to Miss Margaret Dunn of Lancaster, Pa., in Jacksonville, September 1.

MAURICE JULIAN ROTKOW, Des Moines, Iowa, to Miss Johanna Raskin of Savannah, Ga., September 24.

WILLIAM H. STUDLEY, Shorewood, Wis., to Mrs. Doherty A. Spofford of New York, September 14.

ROBERT A. GILREATH, Hendersonville, N. C., to Miss Marie E. Hench of Defiance, Ohio, in August.

GLEN LUKE YATES, Belleville, N. J., to Miss Frances Sinclair Backs of Glen Ridge, September 7.

GUSTAVE A. ROY to Miss Gertrude R. Fearon, both of Kansas City, Mo., September 20.

FRANK READ HOPKINS to Miss Nancy Scott Adams, both of Lynchburg, Va., September 14.

PAUL HOGG, New York, to Miss Dorothy Elizabeth Williams of Norfolk, September 21.

EUGENE E. POLGAR, Bethlehem, Pa., to Miss Anna Munchak of Scranton, September 7.

Deaths

Bundy Allen ♂ Tampa, Fla., St. Louis College of Physicians and Surgeons, 1912, member of the House of Delegates of the American Medical Association, 1930-1932 and 1935, member of the American Roentgen Ray Society and the American College of Radiology, member and past president of the Radiological Society of North America, on the staff of the Centro Asturiano Hospital, aged 50, was killed, November 25, in an automobile accident.

John Morse Rehfsch ♂ San Francisco, University of California Medical School, San Francisco, 1915, member of the Radiological Society of North America, formerly assistant clinical professor of medicine (radiology), Stanford University School of Medicine, assistant pathologist at his alma mater, 1915-1917, and instructor in medicine, 1919-1923, aged 42, died, September 18, of aortic and mitral stenosis and myocardial hypertrophy.

Pierre Zéphyr Rhéaume, Montreal, Que., Canada, School of Medicine and Surgery of Montreal, 1900, professor of operative surgery, University of Montreal Faculty of Medicine, fellow of the American College of Surgeons, served with the Canadian Army during the World War, surgeon in chief to St. Luke's Hospital, aged 58, died, September 18.

William Collins Pumpelly, Fort Pierce, Fla., College of Physicians and Surgeons, Baltimore, 1903, member of the Florida Medical Association, veteran of the Spanish-American and World wars, at one time professor of pharmacology, chemistry and botany, College of Pharmacy, Mercer University, Macon, Ga., aged 58, died, September 18.

Cyrus Ulysses Johnson, West Berkshire, Vt., University of Vermont College of Medicine, Burlington, 1888, member of the Vermont State Medical Society, past president of the Franklin County Medical Society, member of the state legislature, aged 72, died, October 14, in St. Albans (Vt.) Hospital, of cerebral hemorrhage.

Joseph Abel Thibodeau ♂ Rumford, Maine, College of Physicians and Surgeons, Boston, 1912, member of the New England Society of Psychiatry, past president of the Oxford County Medical Society, aged 51, on the staff of the Rumford Community Hospital, where he died, September 17, of subarachnoid hemorrhage.

Theophilus Erskine Ross ♂ Hattiesburg, Miss., College of Physicians and Surgeons, Baltimore, 1888, in 1928 member of the House of Delegates of the American Medical Association, past president of the Mississippi State Medical Association, fellow of the American College of Surgeons, aged 71, died, September 29.

Dell Ewing Graham ♂ Ottumwa, Iowa, State University of Iowa College of Medicine, Iowa City, 1902, fellow of the American College of Surgeons, aged 58, on the staffs of the City Hospital and St. Joseph's Hospital, where he died, September 22, of malignant hypertension and cerebral hemorrhage.

Ernst Philip Raab, Belleville, Ill., University of Pennsylvania Department of Medicine, Philadelphia, 1881, member of

the Illinois State Medical Society, formerly president of the school board and library board, on the staff of St. Elizabeth's Hospital, aged 75, died, September 21, of heart disease

Patrick Joseph Ryan, Hartford, Conn., University of Buffalo (N. Y.) School of Medicine, 1899, member of the Connecticut State Medical Society, aged 70, for many years on the staff of St. Francis Hospital, where he died, September 29, of suppurative appendicitis and peritonitis

John Lear, Trexlertown, Pa., University of Pennsylvania Department of Medicine, Philadelphia, 1889, member of the Medical Society of the State of Pennsylvania, at one time head of the department of biology, Muhlenberg College, Allentown, aged 76, died, October 7, of chronic myocarditis

Charles David Carter, De Kalb, Ill., Rush Medical College, Chicago, 1883, member of the Illinois State Medical Society, past president of the De Kalb County Medical Society, on the staff of St. Mary's Hospital, aged 75, died, November 14, of chronic nephritis and uremia

Frank A. Rich, Burlington, Vt., University of Vermont College of Medicine, Burlington, 1893, member of the Vermont State Medical Society, formerly professor of veterinary science at his alma mater, aged 74, died, September 25, of pulmonary hemorrhage and chronic bronchiectasis

Harry Alexander Lindsay, Sidney, Ohio, State University of Iowa College of Medicine, Iowa City, 1906, served during the World War, aged 63, on the staff of the Wilson Memorial Hospital, where he died, in September, of a self-inflicted bullet wound

Conrade Alleyne Howell, Columbus, Ohio, Homeopathic Hospital College, Cleveland, 1888, Ohio Medical University, Columbus, 1901, fellow of the American College of Surgeons, served during the World War, aged 68, died, September 21, of pneumonia

J. Frank Small, York, Pa., University of Pennsylvania Department of Medicine, Philadelphia, 1889, member of the Medical Society of the State of Pennsylvania, director of public health of York, aged 70, died, October 20, of coronary thrombosis

Hugh Ferguson Parrish, Portsmouth, Va., University of Vermont College of Medicine, Burlington, 1893, Bellevue Hospital Medical College, New York, 1895, member of the city council, aged 63, died, October 7, probably of angina pectoris

William Lewis MacDonald, Boston, Harvard University Medical School, Boston, 1865, member of the Massachusetts Medical Society, formerly a dentist aged 101, died, September 24, in Malden, of arteriosclerosis and chronic myocarditis

Francis A. Graham, Lincoln, Neb., Omaha Medical College, 1889, for eight years county coroner, member of the county insanity board, for many years on the staff of St. Elizabeth's Hospital, aged 73, died, October 31, of septicemia

Lloyd Edmund McFarlane, Manhattan, Kan., University of Minnesota Medical School, Minneapolis, 1921, member of the Kansas Medical Society, aged 39, died, September 26, in Rochester, Minn., of jejunal ulcer and bronchopneumonia

James Allen Shackelford, Ranger, Texas, Tulane University of Louisiana Medical Department, New Orleans 1912, member of the State Medical Association of Texas, aged 48, died, September 21, of coronary occlusion

Friend Palmer, Cerrillos, N. M., Cleveland College of Physicians and Surgeons, Medical Department of the University of Wooster, 1887, aged 73, died, September 24, in Albuquerque, N. M., of chronic myocarditis

Perry Harris Munger, St. Paul Park, Minn., University of Michigan Department of Medicine and Surgery, Ann Arbor, 1889, aged 74, died, September 8, in Stillwater, of cerebral arteriosclerosis and kidney disease.

Charles Edward Greenfield, Chicago, Rush Medical College, Chicago, 1886, member of the Illinois State Medical Society, aged 75, died, November 3, in the Presbyterian Hospital, of bronchopneumonia

Edwin Sheridan Day, Earlham, Iowa, College of Physicians and Surgeons of Chicago 1894, aged 66, died, September 17, at the Iowa Methodist Hospital, Des Moines, of hypertensive heart disease.

Charles Albert Macrum, Portland, Ore., University of Michigan Homeopathic Medical School, Ann Arbor 1889, aged 73, died, September 7, in the Good Samaritan Hospital of lobar pneumonia

Fred Walter Murrey, Caldwell, Ohio, Keokuk (Iowa) Medical College, College of Physicians and Surgeons 1900, president of the board of education, aged 62, died, September 15, of tuberculosis

Taylor Rice Jackson, Chariton, Iowa, College of Physicians and Surgeons of Chicago, School of Medicine of the University of Illinois, 1897, aged 65, died, September 12, of septic sore throat

Evert Harwood Ostling, Lewellen, Neb., State University of Iowa College of Medicine, Iowa City, 1919, aged 42, died, September 28, in the Good Samaritan Hospital, Columbus, of septicemia

Christopher George Lehman, Detroit, Michigan College of Medicine and Surgery, Detroit, 1901, member of the Michigan State Medical Society, aged 63, died, September 27, of encephalitis

Edward S. Meers, Kenosha, Wis., Yale University School of Medicine, New Haven, Conn., 1874, aged 84, died, September 17, of cerebral hemorrhage, chronic nephritis and chronic myocarditis

Edward William Jackson, Rochester, N. Y., Albany Medical College, 1907, fellow of the American College of Physicians, aged 58, died, October 2, in Williamson, of cerebral thrombosis

Roy Colony Alt, Cedar Rapids, Iowa, Jefferson Medical College of Philadelphia, 1913, member of the Iowa State Medical Society, aged 48, died, September 10, of myelogenous leukemia

Emily L. Hill, Gloversville, N. Y., Hahnemann Medical College and Hospital, Chicago, 1894, aged 74, died, September 22, of hyperthyroidism and valvular heart disease.

Lawrence S. Pearce, Falkner, Miss., University of Louisville (Ky.) Medical Department, 1875, Confederate veteran, aged 88, died, September 18, of hypostatic pneumonia.

Asher Franklin Snyder, Mount Joy, Pa., University of Pennsylvania Department of Medicine, Philadelphia, 1908, aged 50, died, October 5, of coronary thrombosis

Robert John Trimble, Queenston, Ont., Canada, University of Toronto Faculty of Medicine, 1875, L.R.C.S., L.R.C.P., Edinburgh, 1876, aged 86, died, September 16

George F. Sheedy, New York, Yale University School of Medicine, New Haven, Conn., 1902, aged 58, died, October 13, in St. Luke's Hospital, of gastric ulcer

Howard Gillespie Myers, New York, Bellevue Hospital Medical College, New York, 1887, aged 73, died, September 12, in Wilton, Conn., of arteriosclerosis

William James Pearce, Dodgeville, Wis., Rush Medical College, Chicago, 1881, aged 78, died suddenly, September 24, probably of heart disease.

James Albert Snapp, Goshen, Ind., Detroit College of Medicine, 1891, aged 70, died, September 28, of cerebral hemorrhage and arteriosclerosis

James Alfred Maloney, Chicago, Temple University School of Medicine, Philadelphia, 1910, aged 49, died, August 27, of chronic myocarditis

Simon Samuel Albert Miller, Chicago, New Orleans University Medical College, 1900, aged 61, died August 20, of chronic myocarditis

Robert Moorhead Neilson, St. Jerome, Que., Canada, Laval University Faculty of Medicine, Quebec, 1915, aged 45, died, September 27

Lester Samuel Lang, Oneonta, N. Y., Syracuse University College of Medicine, 1907, aged 56, died, September 24, of angina pectoris

Nathan Farmer Davis, Chandler, Ariz., Curtis Physio-Medical Institute Marion, 1897, aged 81, died, September 26, of arteriosclerosis

William Abraham Groves, Fergus, Ont., Canada, University of Toronto Faculty of Medicine, 1903, aged 58, died, September 26

Alfred Roscoe Andrews, Auburn, N. S. Canada, Halifax Medical College, Halifax, N. S., Canada, 1879, aged 76, died in September

Alexander Chittick, Peoria, Ill., National Medical University Chicago, 1904, aged 62, died, October 9, of cerebral hemorrhage

Jonathan W. Lewis, Driggs, Ark. (licensed in Arkansas in 1903), aged 84, died, August 8, of uremia and heart disease.

Robert Jesse Teeter, Waterford, Ont., Canada, Trinity Medical College, Toronto 1893, aged 67, died, September 14

Frederick F. Kitzing, Chicago, Rush Medical College, Chicago, 1905, aged 56, died July 18, of cerebral hemorrhage

Charles Mackay, Seaforth, Ont., Canada, Trinity Medical College, Toronto 1891, aged 73, died, October 16

MORE NOSTRUMS IN RETROSPECT

Condensed Reports on "Patent Medicines" Previously Dealt With in Greater Detail

Some months ago there were published in this department of THE JOURNAL greatly condensed reports of much longer and detailed articles published previously on several widely-advertised "patent medicines." The material that follows gives in brief form statements regarding additional products that have already been dealt with in the past more extensively.

Laxative Bromo Quinine—Many years ago this product was advertised under the claims that it "cures a cold in one day." The preparation was the subject of an article in this department of THE JOURNAL, Nov 27, 1915. At that time it was reported that the A M A Chemical Laboratory had found that each tablet of Laxative Bromo Quinine contained as its essential ingredients 2 grains of acetphenetidin, $\frac{1}{2}$ grain of caffeine, $\frac{1}{2}$ grain of quinine or cinchona alkaloids with aloe or aloin as a laxative. It was brought out in the article that while the name Bromo Quinine gives the impression that bromine and quinine were the important ingredients, analysis disclosed that the bromide content was only $\frac{1}{200}$ of the whole, corresponding to about $\frac{1}{30}$ of a grain of potassium bromide or $\frac{1}{500}$ part of a Pharmacopoeial dose. The article also stated that the formula for the preparation had apparently changed about the time the National Food and Drugs Act went into effect. An analysis made for the American Medical Association in 1905 indicated that in addition to the laxative principle, the tablets contained acetanilide, quinine sulphate and caffeine, but no trace of bromine. An analysis made by the state chemists of North Dakota and published in 1907 also failed to show the presence of bromine. The Federal Trade Commission in June 1935 reported that the Grove Laboratories, Inc. of St. Louis, exploiters of Groves Laxative Bromo Quinine Tablets had entered into a stipulation with the Commission to cease claiming that its nostrum "is a cold remedy." Yet an advertisement that appeared in the Chicago Tribune Nov 7 1935, read in part as follows: "KILL THAT COLD! Don't Merely Coddle It with Half-Way Measures! A cold is nothing to trifle with! It may end seriously. A cold, being an internal infection, calls for an internal treatment. It also calls for a cold preparation and not something good for a number of other things as well. Groves Laxative Bromo Quinine is what a cold requires. It is expressly a cold tablet." The 1935 trade package declares—as the law requires—that each Laxative Bromo Quinine tablet contains one grain of acetanilide! It thus appears that the most powerful drug in the nostrum has always been a heart-depressing coal-tar product. First acetanilide, then acetphenetidin (phenacetine) and now again acetanilide.

Murine—Before the passage of the Food and Drugs Act, the "eye remedy" Murine was described on the trade package as "a positive cure for sore eyes," etc. Following the passage of the law, Murine became "a reliable relief for sore eyes," etc. In the earlier days the exploiters of Murine also conducted a school of spectacle fitting known as the Northern Illinois College of Ophthalmology and Otology. It conferred at least seven "degrees" and issued ornate "diplomas" that according to the college's catalog, would "frame handsomely 28 x 28 inches." Twenty-seven years ago (November 1908) there was published in this department of THE JOURNAL an extensive article on Murine and its method of exploitation. Considerable information was given regarding the alleged college operated by those who were interested in Murine. In this article there were given the results of an analysis made in the Chemical Laboratory of the American Medical Association. From their examination, the Association's chemists concluded that Murine was essentially a water solution of borax (about 12 grains to the fluid ounce) containing a trace of berberine or some golden seal preparation. At that time the manufacturers of Murine made no pretense of giving information regarding the composition of their product. About 1922, however, when a seeming frankness was the order of the day in

the "patent medicine" business, the Murine carton listed what were said to be the "ingredients used in the compounding of Murine." According to the cartons at that time, these ingredients were Geranium Maculatum [Cranesbill], C P Boracic Acid, Berberine Hydrochlorid, Podophyllum Peltatum [May-apple], Pilocarpus [Jaborandi], Chloramine-T, Rhubarb, Glycerine, Potassium Sesquicarbonate, Distilled Water, Xanthoxylum [Prickly-ash]. In a reprint of the Murine article published in the 1923 edition of the pamphlet "Miscellaneous Nostrums," prepared and issued by the Bureau of Investigation, attention was called to two facts: first, that if chloramine-T were present in Murine in 1923, the formula had obviously been changed, for chloramine-T was not introduced into medicine until 1916; second, that chloramine-T, although declared as one of the ingredients used in making Murine, was not even found in the 1923 preparation! In fact chemists would not have expected to find it, as chloramine-T is incompatible with boric acid. The present (1935) cartons of Murine no longer carry on them the alleged list of ingredients.

Western Medical Corporation—This is one of a number of medical mail-order concerns operating from the same address and putting out a number of nostrums. Under its earlier name, Western Medical Association, it was the subject of an article in this department of THE JOURNAL Jan 28, 1922, and again the subject of a later article under its present name Aug 5, 1933. The name of Harry L. James, M.D., has been played up as the "Directing Physician." This man was reported to be vice-president of the corporation. Part of the advertising ballyhoo has been a six-page puff of Harry L. James, written by Harry L. James. While the advertising might lead the public to believe that James is peculiarly well qualified to treat cases of epilepsy, he is quite unknown to scientific medicine in this field. The analysis made of the so-called treatment put out by the concern when it was known as the Western Medical Association showed its essential ingredient to be phenobarbital (luminal). There were also some so-called digestive tablets and a laxative.

Nurito—This "patent medicine" was first dealt with in this department of THE JOURNAL of Aug 10, 1912. It was analyzed at that time in the A M A Chemical Laboratory and was found to consist of milk sugar, phenolphthalein and amidopyrine (pyramidon). In August 1914 the Food and Drug Administration issued a Notice of Judgment (No 2997) in which it was declared that Nurito had been found misbranded in violation of the National Food and Drugs Act. They reported at the time that the federal chemists found both amidopyrine and milk sugar in Nurito, but no statement was made regarding the presence of phenolphthalein. In 1927 a Chicago daily newspaper was offered the Nurito advertisement. The advertising department of the paper, in asking the Bureau of Investigation for information on Nurito, stated that a representative of the concern that put out Nurito had declared that amidopyrine (pyramidon) had been removed from Nurito and that the "patent medicine" at that time contained aspirin, phenolphthalein, colchicin salicylate, caffeine and milk sugar. No amounts were stated. Whether this represents the essential ingredients in Nurito today, we do not know. In May 1934 the Federal Trade Commission reported that it had directed the Nurito Company of Chicago to discontinue representing the efficacy of its product Nurito as a treatment for neuritis, rheumatism, neuralgia, sciatica and lumbago. The Commission added that Nurito would be a dangerous product to use in some cases and that certain ingredients were likely to produce toxic effects.

Min-amin—This was the subject of an extended article published by the Bureau of Investigation in THE JOURNAL, Jan. 26, 1935. It was brought out in the article that no information was given on or in the trade package (which is all that is subject to the requirements of the National Food and Drugs Act) regarding the composition, other than the vague statement that it was "a combination of pure food concentrates containing minerals and vitamins." A booklet sent out by those who sold Min-amin stated that the product contained 21.85 per cent protein, 14.4 per cent crude fat, 54.05 per cent carbohydrates, 0.8 per cent crude fiber, and 3 per cent ash. The booklet stated, also, that the fuel value of a teaspoonful of Min-amin was 41.84 calories. A report from the A M A Chemical Labora-

tory was given in some detail and the chemists expressed the opinion that Min-amin was essentially powdered wheat germ. The instructions that went with Min-amin were, in effect, that the obese should eat no breakfast and no luncheon, but take instead of each of these meals a rounded teaspoonful of Min-amin in an eight-ounce glass of freshly-made, unstrained orange juice. THE JOURNAL's article closed with the statement that there seemed to be nothing novel or original in Min-amin and that other food powders had appeared on the market in the past year or two recommended in the treatment of obesity as substitutes for breakfast and luncheon.

Correspondence

IMPEDANCE ANGLE TEST FOR THYROTOXICOSIS

To the Editor—In 1933 one of us (M. G. W.) published a paper on the polarization capacity of the skin as an index of thyroid function (*Endocrinology* 17:299 [May-June] 1933). Three months later there appeared a paper by Dr. M. A. B. Brazier (*Lancet* 2:742 [Sept. 30] 1933) dealing with the same subject but designating the method as measuring the impedance angle. In THE JOURNAL, October 12, page 1211, in reply to a query on the impedance angle test for thyrotoxicosis, you state that "American workers fail to corroborate the English observations." This statement requires correction. In the paper published in *Endocrinology* calling the method a polarization capacity, the results substantially agree with those of Dr. Brazier with the following difference. While the polarization capacity as well as the impedance angle was found to be high in thyrotoxicosis, we found that the polarization capacity was not correlated with the basal metabolic rate. Dr. Brazier, on the other hand, finds that the impedance angle can be correlated with the basal metabolic rate. Be that as it may, it is important to point out the fact that the measurements made by Dr. Brazier and ourselves express the same basic phenomenon.

On reading over the various articles dealing with the subject, one may be led to believe that different quantities were being measured by the different workers (Lueg, Grassheim, Wohl, Brazier) since one worker says he is measuring the impedance angle while another worker says he is measuring the polarization capacity of the skin. All the measurements were concerned with the impedance of the human body to an alternating current. To be sure they used different frequencies of current and somewhat different techniques as well as different apparatus, which would certainly be apt to give results not in general agreement, but the quantities measured in every case were closely related to the impedance of the body to the alternating current passed through the body.

In any circuit carrying an alternating current there are three fundamental quantities involved, namely, a pure resistance, a reactance due to the capacitance of the circuit, and a reactance due to any inductance in the circuit. No circuit carrying an alternating current is entirely free of any of these quantities, but it is true that circuits are made in which either the reactance due to the capacitance or to the inductance are made negligibly small and can therefore be neglected. We believe that all the workers interested in this problem have implied that the inductance was negligible, since they have all omitted it from their considerations. We believe they are justified in taking this point of view. Hence the circuit contains only the two remaining quantities, and we have for the total impedance of the circuit

$$Z = \sqrt{R^2 + \left(\frac{1}{C\omega}\right)^2}$$

R = pure resistance
 C = capacity
 ω = 2π times the frequency

Now since the currents used were harmonic functions of the time the pure resistance and the reactance due to the capacitance can be plotted graphically and added as vector quantities. The

total impedance is then the vector sum of the two quantities, and the impedance angle is the angle between the total impedance vector and the resistance vector. It should be stated here that these quantities are not really vector quantities but can be treated as such when the impressed electromotive forces are harmonic. To determine the impedance angle in a circuit containing only resistance and capacitance, one must measure the capacitance that must be inserted into the circuit in order to bring the current in phase with the voltage. This is exactly what all the workers have done and hence they have all been measuring the same basic phenomena. They do express different points of view as to the causes of the capacity of the body, but as to the merits of these points of view they are yet to be determined.

MICHAEL G. WOHL, M.D.

Associate Professor of Medicine, Temple
University Medical School

ROSCOE STINETORF, Ph.D.

Member of Department of Physics,
University of Pennsylvania

Philadelphia.

To the Editor—Regarding the communication from Dr. Killoran on the impedance angle test for thyrotoxicosis, which appeared in *Queries and Minor Notes* in the issue of October 12, I note that in your answer no reference was made to a publication by Wilson and myself in the *Lancet*, showing that no correlation existed between the basal metabolic rate and the impedance angle test. The article referred to is Robertson, J. D., and Wilson, A. T. A Combined Study of the Basal Metabolism and Impedance Angle in Thyrotoxicosis and Myxedema, *Lancet* 2:1158 (Nov. 24) 1934. Our observations anticipated those of the American workers by some six months.

J. DOUGLAS ROBERTSON, M.B.,

Middlesex Hospital Medical School,
London.

LYMPHOCYTIC MENINGITIS

To the Editor—Considerable interest has been shown by medical writers in the syndrome variously called aseptic, idiopathic, epidemic and acute lymphocytic meningitis. It was first clearly described by Wallgren (*Acta paediat* 4:158, 1925) and subsequently it formed the subject of a comprehensive article in the American literature by Viets and Watts (*THE JOURNAL*, Nov. 16, 1929, p. 1553).

At about this time I encountered a case with many similar characteristics at the Boston Psychopathic Hospital. This patient showing cerebral symptoms of an organic nature was found to have the typical signs and blood picture of infectious mononucleosis, commonly known as "glandular fever." Because of the uniqueness of the condition, the case was reported in detail under the title "Involvement of the Central Nervous System in a Case of Glandular Fever" (*New England J. Med.* 205:1238 [Dec. 24] 1931). Simultaneously there appeared a similar report in the Scandinavian literature by A. H. Johansen (*Acta med Scandinav* 76:269, 1931). In both of these articles the relationship between lymphocytic meningitis and infectious mononucleosis was emphasized. My attention was recently called by Dr. Edwin M. Cole (personal communication) to another case of this sort, showing the typical picture of infectious mononucleosis and the syndrome of mild meningitis.

During the last few years many authors, notably S. A. K. Wilson (*J. Neurol. & Psychopath.* 10:36 [July] 1929) and Reiche (*Ztschr. f. klin. Med.* 110:506, 1929) have stressed the association of central nervous system involvement with various generalized infections, such as postvaccinal encephalitis and the acute exanthems. These clinical observations have been subjected to experimental investigations of possible etiologic factors. From the latter standpoint attention has been repeatedly focused on the filtrable viruses.

Recently interest in lymphocytic meningitis was stimulated by some experimental investigations of a filtrable virus isolated from patients with this disease. The work of Armstrong (*Pub Health Rep* 49 1019 [Aug 31] 1934) and of Rivers and Scott (*Science* 81 439 [May 3] 1935) indicates that a filtrable virus is the causative agent of acute lymphocytic meningitis and tends to prove that the disease is a clinical entity.

There are many discrepancies in the clinical and serologic observations in these cases, and the constancy of the signs and symptoms of this disease is questionable. It appears that there are many conditions, sometimes called encephalitis, in which this benign meningitic syndrome occurs. There are also known systemic diseases accompanied by changes in the central nervous system and these are not classed as clinical entities. Furthermore, some of the blood diseases of obscure etiology sometimes show central nervous system involvement. The best illustration of this phenomenon is furnished by the three case reports mentioned of infectious mononucleosis with involvement of the central nervous system. In the first two cases the spinal fluid cellular reaction parallels the cell counts of the peripheral blood, which indicates a close relationship between the two systems and between the diseases infectious mononucleosis and lymphocytic meningitis.

It seems to me that the crux of the whole problem lies in the larger concept of various systemic diseases of known and unknown etiology, giving rise to changes in the central nervous system. I am inclined to believe that such diseases as infectious mononucleosis may produce cerebral changes, and conversely that so-called lymphocytic meningitis, like certain of the encephalitides, is merely symptomatic of some as yet unknown systemic disease.

SAMUEL H. EFSTEIN, M.D., Boston

Queries and Minor Notes

ANONYMOUS COMMUNICATIONS and queries on postal cards will not be noticed. Every letter must contain the writer's name and address but these will be omitted on request.

OXYGEN INHALATION IN PNEUMONIA

To the Editor.—More than a year ago in answer to an inquiry you published an article on the use of oxygen in pneumonia and described the technic of administration. In this article you described two types of nasal inhalers, one of them by Bullowa, and a device by which the rate of flow might be gaged by the diameter of its orifices. Surgical supply houses here seem unable to obtain these articles. I wish to make the following inquiries: 1. Are the nasal inhalers better tolerated by patients especially children than nasal catheters? 2. Is the administration of oxygen more effective when they are used? 3. Where may they be purchased? Please omit name.

M D Oklahoma

ANSWER.—The advice in Queries and Minor Notes in *THE JOURNAL*, Jan. 27, 1934, page 311, was intended to instruct physicians to use industrial oxygen and, in an emergency, how to utilize an industrial oxygen regulator by interposing a slug perforated with a drill hole of suitable size in the rubber tubing leading from it.

If one purchases a regulator, the best type is a two-stage regulator with a variable orifice or float gage because it indicates the amount of oxygen actually flowing. Once calibrated it does not become inaccurate by use or overstrain. Dial gages are made with Bourdon tubes, which are subject to overstrain. They may indicate a high flow rate though there is no escape of oxygen from the catheter or inhaler. This is readily demonstrable to any one who pinches the tubing and observes the float and the dial.

1. Nasal inhalers with the oxygen discharged just within the nares are frequently better tolerated, especially by children, than soft nasal catheters inserted to the pharynx.

2. The inhaler or metal catheter with rubber tips inserted one-fourth inch into the nostrils is frequently more effective than a soft catheter, because oxygen is admitted to the two nostrils at the same time, and more oxygen can escape through a well made cannula than through even two catheters of size 10 French. Under 3 inches of water pressure no more than 15 liters per minute will escape from a single No. 10 French

catheter of wide bore. The openings in small catheters frequently become obstructed by mucus, which is sometimes due to irritation of the catheter. When oxygen escapes at the same rate from a large and from a small opening, the pressure against the mucous membranes is less when the opening is large, and the mucous membranes are irritated less. When measured by the concentration of oxygen in the alveolar air, the administration of oxygen by the pharyngeal catheter had only slight or no advantage over the administration by a nasal inhaler.

3. Several varieties of inhalers or metal nasal catheters should be available to fit various physiognomies. The Bullowa inhalers, adult size, can be purchased from the F. A. Noble Company, Inc., 2136 Seventh Avenue, New York; the children's size from the Foregger Company, 55 West Forty-Second Street, New York. The Connel, Sanborn and Gwathmey inhalers may be purchased from the Foregger Company and many other surgical supply houses. Inhalers should be made of malleable brass without constriction at the fork. The cross bar for attachment to the forehead should be adjustable on the stem and held in place with an adequate spring. Children size inhalers should permit the free discharge of 6 liters of oxygen per minute measured with a variable orifice or float gage, and the adult size should permit the discharge of 15 liters per minute. Oxygen regulators approved by the Council on Physical Therapy may be purchased from dealers in oxygen and from many surgical supply houses. The Council has approved a float type regulator made by the Air Reduction Company and a dial type regulator made by the Linde Air Products Company.

HYPERTENSIVE DISEASE

To the Editor.—Last October I discovered that I had a blood pressure of 180 systolic 100 diastolic. I am 54 years of age. Since last October the blood pressure has been averaging 180/100 but a few days ago it went to 200/120. I have had two electrocardiograms made which were pronounced normal. The urine is reported as being normal. On roentgen examination my teeth appear to be sound. The chest and heart have been roentgenographed and no abnormality found. The tonsils were removed in 1919, but I was off work for a year at that time with a systemic infection but have been physically fit since then until last October. I sleep well and have a good appetite. There is a constant dull pain in both temples. There is a sense of fullness in the ears at times. I have no pep. I tire easily. I am forgetful. There is some shortness of breath at times. I am of a nervous temperament. The bowels are regular. I have gotten up once or twice at night to urinate for several years. The Wassermann reaction is normal. I have not been working hard for the last two years but until that time I was putting in long, hard hours. My mother died at 75 with a stroke. My father died at 67 with what was supposed to be angina. I have taken sodium nitrite, bismuth subnitrate bromides, phenobarbital and potassium thio cyanate without results. If you can give any advice from this meager history, it will be greatly appreciated. Please omit name.

M D, Indiana

ANSWER.—It would be of considerable interest and value to know what the arterial tension was a year ago and also a year before that. Knowledge of the rate of progression of hypertensive disease is valuable from both the prognostic and the therapeutic point of view. It is quite possible that the "systemic infection" in 1919, which required a year for recuperation, may have initiated the present disturbance.

Failure to obtain benefit from the forms of management already tried may be due to one or more of several factors. In the first place, the effects of medication with sedatives and/or the milder vasodilators may require several weeks before objective benefit is apparent, it is therefore possible that longer trial would be advantageous. The effectiveness of such management is largely nullified by intense apprehension. In the second place, arteriosclerosis may have already occurred and no sedative or vasodilator medication will then be of value. This may be quickly determined by the amylin nitrite test (Steghitz, E. J. *Arterial Hypertension, Arch. Int. Med.* 46 227 [Aug.] 1930, *Illinois M. J.* 62 414 [Nov.] 1932). It is well known that hypertensive arterial disease initiated by influenza or similar systemic infection often progresses rapidly to extensive arteriosclerosis which is irrevocable and not amenable to therapeutic correction. The third explanation for the failure of medical management is that some active etiologic factor or factors yet remain undiscovered and therefore uncorrected. This is the most probable reason at least from the data available, especially as the arterial tension appears to have increased still further recently. Thorough, painstaking search for etiologic factors is certainly indicated. Anemia (often not severe but still significant), thyroid dyscrasia, mild chronic plumbism (commonly overlooked), foci of infection other than the teeth, mild arsenic poisoning, and impairment of the renal function must all be carefully and fully ruled out. Many other factors of etiologic significance must also be considered should these prove "negative." The fact

that the "urine was reported normal" does not rule out renal functional impairment, this can be done only after functional evaluation by renal function tests. The more important of these include the concentration test (Fishberg), the diuresis concentration test (Mosenthal), the urea clearance test and, perhaps, the sodium ferrocyanide excretion as a measure of glomerular efficiency (Stieglitz, E. J., and Knight, A. A. Sodium Ferrocyanide as a Clinical Test of Glomerular Efficiency, *THE JOURNAL*, Dec 8, 1934, p 1760). The relative importance of constitutional or hereditary influences and added insults from various intoxications requires evaluation.

Advice then must be along these general lines. Further studies should attempt to determine and reveal unrecognized but active initiating etiologic factors and the correction of these whenever found feasible. Long continued sedation either through the nervous system (as with bromides) or more directly of the arterioles (as with bismuth subnitrate) is certainly indicated. Such management may require several weeks' continuance before benefit is apparent. Attention to diet, the correction of anemia and an adequate intake of fluid are essential. The newer surgical methods of attack, through denervation of the adrenals, partial adrenalectomy and/or extensive sympathectomy, are still almost wholly experimental and thus far have failed to yield results at all commensurate with the risks involved.

'ADVANCES IN THERAPEUTIC TECHNIC

To the Editor—The paper by Dr. Bernard Fantus, *Advances in Therapeutic Technic* (*THE JOURNAL*, Sept. 14, 1935, p. 877) is interesting but I am not able to understand several points. Failure to have the National Formulary VI at hand makes the situation more difficult for me. I understand that iso-alcoholic elixir is aromatic elixir with a changeable percentage of alcohol whereas the official aromatic elixir has a stable content of about 23 per cent alcohol. Does iso-alcoholic elixir mean that the aromatic elixir should contain the same percentage as the alcoholic extract of the drug in question? e. g. should iso-alcoholic elixir in prescription 1 contain about 70 per cent alcohol because tincture of digitalis contains about 70 per cent? 2. The statement is made before prescription 5: "For nonextractive substances the lowest alcoholic strength of iso-alcoholic elixir should be chosen." As terpin hydrate requires strong alcohol for solution the pharmacist will employ the high alcoholic elixir as the vehicle. I cannot understand this explanation. What does iso-alcoholic elixir mean in regard to nonextractive substances as given in prescription 5? What would be the difference between (a) terpin hydrate 50 iso-alcoholic elixir ad 60.0 and (b) terpin hydrate 50 aromatic elixir U. S. P. ad 60.0? I understand that elixir terpin hydrate N. F. contains 0.08 to one teaspoonful whereas a and b would contain about 0.4 (one teaspoonful 5 cc. as it really is). 3. I was unable to find 'calbromen' in the Epitome fourth edition though calobren is mentioned in the description of the latter however does not indicate that calobren is composed in candy form. How should the candy form be prescribed? 4. May I ask you another question not directly pertaining to Dr. Fantus's paper? What form of prescription would you advise as an iron tonic for children in liquid and which one in candy form but not a ready commercial preparation and how to avoid the high content of alcohol if prescribed as an elixir? Can aromatic elixir with 23 per cent be considered nonirritating if prescribed for children and how about prescribing it for a patient suffering from chronic gastritis a condition in which alcohol should be avoided in any form whatever? As most of the tonics or hematinics contain a high percentage of alcohol if tonics are to be given is there any way out of that quandary by means of iso-alcoholic elixir? Going through all the prescriptions I noticed that there must be a mistake in prescription 4 cannabis (fluidextract) being given as 15.0! Thus prescription 4 would contain 1 cc. per teaspoonful the dosage however being 0.1 cc! What about prescription 12? There the dosage would be 1.25 per tablespoonful. Has that dosage been wanted by the author?

H. MARKT M.D., Astoria, L. I. N. Y.

To the Editor—I have been asked by my doctor to stock several items which I have been unable to locate from local jobs. The items referred to are listed on pages 879 and 880 of *THE JOURNAL*, Sept. 14, 1935. The items in question are iso-alcoholic elixir and alkaline elixir eriodictyon. You say in the same paragraph that the formula can be found in Recipe Book II. Will you please advise me as to where I can purchase these items or where I can find the formula for making them?

CHARLES HORNE, Druggist, Greenville, S. C.

ANSWER.—For the production of iso-alcoholic elixir the pharmacist is given, in N. F. VI, a formula for a low alcoholic elixir and a high alcoholic elixir, which are to be mixed in the proportion required to produce a perfect solution with the medicament, whenever the physician prescribes iso-alcoholic elixir. The formulas for these two elixirs are as follows:

Low-Alcoholic Elixir

| | |
|---------------------------|---------|
| Compound spirit of orange | 10 cc. |
| Alcohol | 100 cc. |
| Glycerin | 200 cc. |
| Sucrose | 320 Gm. |

Distilled water a sufficient quantity to make 1 000 cc.

Mix the alcohol, glycerin and 500 cc. of distilled water add the compound spirit of orange, agitate thoroughly from time to time and let stand for twenty-four hours. Filter through a hard paper filter, return

ing if necessary the first portions of the filtrate until it passes through clear. Dissolve the sucrose in the filtrate by agitation or percolation, and add enough of the solvent mixture to make the product measure 1 000 cc.

Alcoholic content From 8 to 10 per cent by volume of ethyl alcohol.

High-Alcoholic Elixir

| | |
|---------------------------|---------|
| Compound spirit of orange | 4 cc. |
| Saccharin | 3 Gm. |
| Glycerin | 200 cc. |

Alcohol a sufficient quantity to make 1 000 cc.

Dissolve the compound spirit of orange and the saccharin in 700 cc. of alcohol add the glycerin and sufficient alcohol to make the product measure 1 000 cc. mix well and filter.

Alcoholic content From 73 to 78 per cent by volume of ethyl alcohol.

Table for Adjustment of Iso Alcoholic Elixir

| Low Alcoholic Elixir | High Alcoholic Elixir | Suitable as Vehicle for Preparations of the Following Alcoholic Strengths |
|----------------------|-----------------------|---|
| 1 volume | None | 0-10 per cent |
| 4 volumes | 1 volume | 10-20 per cent |
| 3 volumes | 1 volume | 20-30 per cent |
| 2 volumes | 1 volume | 30-40 per cent |
| 1 volume | 1 volume | 40-50 per cent |
| 1 volume | 2 volumes | 50-60 per cent |
| 1 volume | 3 volumes | 60-70 per cent |
| 1 volume | 4 volumes | 70-80 per cent |
| None | 1 volume | 80-95 per cent |

For liquid galenicals the strength of iso-alcoholic elixir to be used is the same as that of the menstruum or solvent employed in the preparation of the galenical.

When galenicals of different alcoholic strengths are used in the same prescription the iso-alcoholic elixir to be used is to be of such strength as to secure the best solution possible under the circumstances. This will generally be found to be the average of the alcoholic strengths of the several ingredients.

For nonextractive substances the lowest alcoholic strength of iso-alcoholic elixir that will yield a perfect solution should be chosen.

In prescription 1, the proportion of 1 volume of low alcoholic elixir and 3 volumes of high-alcoholic elixir will give a liquid of about 70 per cent of alcohol, which will make a clear solution with tincture of digitalis.

2. For the terpin hydrate prescription the high alcohol elixir is to be used as a solvent, as this quantity of terpin hydrate would not dissolve in alcohol of any lower strength. The elixir terpin hydrate N. F. VI is made to carry 0.07 Gm. of terpin hydrate by means of 40 per cent of alcohol. It is impossible to dissolve the required quantity of terpin hydrate in aromatic elixir.

3. Calbromen is also known as sabromin. It is calcium dibromobenzenate and is recognized in N. N. R. Both it and calcium iodobenzenate U. S. P. can be put up in candy form by mixing them with sugar containing 10 per cent of cocoa, with tincture of vanilla for flavoring and by compressing them in a tablet machine. Formulas for such sweet tablets are found in the Recipe Book published by the American Pharmaceutical Association.

4. There is also in the Recipe Book a prescription for sweet tablets of iron. Such tablets are available on the market. It is easy to prescribe an iron tonic for children in liquid form without the use of an elixir. Such a solution is suggested in the article under discussion as prescription 12, with considerable reduction in dosage, of course. The syrup of cinnamon is made by saturating cinnamon water with sugar, which will be the formula for Syrup of Cinnamon N. F. VI.

The low-alcoholic elixir as well as the various other elixirs of the N. F. contain so low a percentage of alcohol that they may be considered unobjectionable when prescribed for children or patients with chronic gastritis. The aromatic elixir U. S. P. might, on the other hand be sufficiently irritating to be objectionable in chronic gastritis and possibly be slightly intoxicating to a small child.

5. The prescription for fluidextract of cannabis is intentionally made to contain a large dose of the active ingredient, as a smaller dose is not likely to produce any effect and the dose given is not dangerous although it may put the patient into a dreamy state.

In prescription 12 the dose is intended to be 1.25 Gm. per tablespoonful, as the modern tendency is in the direction of large and liberal doses.

The formula for "alkaline elixir of eriodictyon" is as follows:

| | |
|---------------------------------|---|
| Oil of bitter almond | 0.5 cc. |
| Vanillin | 1.0 Gm. |
| Saccharin | 1.5 Gm. |
| Fluidextract of eriodictyon | 30.0 cc. |
| Solution of potassium hydroxide | 27.5 cc. |
| Alcohol | 500.0 cc. |
| Syrup | 350.0 cc. |
| Orange flower water | sufficient quantity to make 1 000.0 cc. |

Dissolve the oil of bitter almond the vanillin and the saccharin in the alcohol then add the syrup. Mix the fluidextract of eriodictyon and the potassium hydroxide solution and add to the solution. Finally add enough orange flower water to make 1 000 cc.

LEUKOPENIA WITH GRANULOCYTOPENIA

To the Editor—A woman aged 30, has a white count ranging between 2,500 and 3,000 cells with a polymorphonuclear leukocyte percentage ranging between 30 and 50. This condition was detected one year ago. All possibility of foci of infection has been ruled out and she has not taken any drugs. The only symptom that she has is extreme fatigue and a general lassitude. I have given her pentanucleotide which has caused the white count to increase temporarily but the reaction is so great that I have not felt like giving it over a prolonged period of time. Recently I have been giving her a sterile milk antigen for nonspecific protein therapy it causes very little systemic reaction and produces practically the same white blood count as when pentanucleotide is used. The patient is at rest most of the time. She has no household duties to perform and spends a portion of her time at complete rest in bed. Any suggestions that you might make in this case will be greatly appreciated.

M D, Georgia.

ANSWER—This case corresponds to the chronic leukopenias with granulocytopenia of unknown origin. This is a poorly understood group of cases. Roberts and Kracke have reported on this subject (*Ann Int Med* 5:40 [July] 1931). In an effort to determine whether any relationship existed between the symptoms of fatigue and exhaustion to the degree of granulocytopenia these authors made a statistical study of 8,000 records of patients seen in private practice who were ambulatory and had no acute illness. They found that one of every four patients may be expected to have a mild granulocytopenia and that it was particularly common in female patients between the ages of 40 and 60. The complaints of weakness, exhaustion or fatigue were twice as frequent in the patients with granulocytopenia as in those with normal white cell counts. Further, there was very little difference in the leukocyte count over a period of ten years. It was the opinion of these authors that there is a definite clinical syndrome consisting mainly of weakness, easy exhaustion, tendency to fatigue, loss of strength and inertia associated with leukopenia and granulocytopenia and that the severity of symptoms is largely dependent on the degree of granulocytopenia. The condition of agranulocytosis merely represented the most severe type. Treatment was not discussed in their paper. However, it is obvious that until more is known concerning the etiology of this group of cases the treatment can only be palliative. The use of repeated small transfusions of about 250 cc of blood is safe and based on scientific fact and clinical experience. If patients who have recovered from this disorder are available, Fisher and Chrisman and Hinton report success with such blood when ordinary blood was without result. Any agent that is capable of stimulating the bone marrow to the production of granular cells is worthy of trial but must be used with caution. Among such agents Kracke lists various nonspecific protein substances vaccines, serums adenine sulphate nucleic acid, colloidal sulphur and the production of sterile abscesses. The use of small stimulating doses of x-rays to the long bones has its exponents but this treatment is potentially dangerous unless the blood is carefully checked and the treatment given by an experienced worker. Massive doses of liver extract by mouth have also been used with success in some cases. Each case should be carefully studied from all possible angles, including endocrine function, and the treatment individualized. For purposes of prognosis bone marrow studies would be of value. If hypoplasia of myelocytic tissue is present the prognosis is invariably poor.

KAHN AND WASSERMANN TESTS

To the Editor—A woman, aged 28, single, was sent to a sanatorium for tuberculosis. She had been classified as a minimal case although her lesions were slight. Her sputum was positive for the tubercle bacillus before admission. At the sanatorium routine Wassermann and Kahn examinations are made and the patient, in the absence of a positive history has shown consistently a 4 plus Kahn and a negative Wassermann reaction both in the sanatorium laboratory and in two other laboratories. After standing several days at room temperature the serum shows a negative Kahn reaction. Can you explain such a reaction for me or tell me an authority or source of information on this subject? The patient has a Vincent's infection of the gums the only other positive finding in her physical examination. Kindly omit name.

M D, Virginia.

ANSWER—It is not unusual to find positive Kahn and negative Wassermann reactions in routine examinations in view of the fact that the Kahn test is more sensitive in detecting syphilis than most Wassermann methods. The Kahn test is not known to give false positive reactions in tuberculosis. In one advanced case of Vincent's angina the Kahn reaction was positive during the height of the infection and was negative after the infection had subsided. This patient was believed to be free from syphilis. The observation that a serum will give a positive Kahn reaction and after the serum has stood for

several days at room temperature, a negative reaction is unusual. It is possible that after the serum had stood for several days at room temperature it may have undergone bacterial contamination, which would, of course, affect the results of all tests for syphilis. It may be also that after the serum had stood for several days at room temperature it was not reheated before the Kahn test was performed. Serums that have stood for twenty-four hours, after having been heated for thirty minutes at 56 C., must be reheated for at least ten minutes at this temperature before this test is performed. If the heated serum has stood for several days, it should be reheated for about twenty minutes. Regarding this phase of the inquiry, it might be well to communicate with the author of the Kahn test (Dr R L Kahn, University of Michigan Hospital, Ann Arbor). Practically all complement fixation and precipitation methods will give an occasional false reaction in tuberculosis. This fact must be kept in mind when interpreting positive reactions in this infection. Yet thorough and extensive search for the possibility of syphilis must be instituted before considering a patient giving a positive reaction as nonsyphilitic.

POSSIBLE SCURVY

To the Editor—Recently I saw an infant aged 5 months, for the first time. The mother received antisyphilitic treatment during pregnancy and the infant had received a total of six treatments, agent unknown. He had received no orange juice or cod liver oil and was on an evaporated milk dilution with Karo. He was fairly well nourished, with only slight evidence of rickets. The temperature was 103 F. He had been crying all day when moved especially when the back or shoulders were touched or pressed on. There was no vomiting or diarrhea. Examination gave no evidence of parenteral infection. There were no clinical signs of scurvy, tetany or syphilitic periostitis. The fontanel was flat, the reflexes were slightly increased, not suggesting either meningitis or poliomyelitis. The formula was diluted, an enema was ordered and 2 ounces (60 cc) of orange juice daily was commenced together with antirachitic measures. One-fourth grain (0.016 Gm) of phenobarbital was administered. On the following day the infant appeared perfectly well and now, three days later, continues to be. There is not the slightest tenderness. From this outline what would you consider to be the most likely diagnosis? Please omit name if published.

M.D, Georgia

ANSWER—This 5 months old infant with a fever of 103 who showed extreme tenderness when moved or touched, had received no orange juice and was on an evaporated milk formula, might well have been suffering with scurvy. The rapidity with which the condition cleared following the administration of orange juice strongly substantiates this diagnosis. Fever is often a symptom of scurvy. There is no evidence to show that the condition was of a syphilitic nature, and a syphilitic periostitis would not be so quickly relieved.

In a young infant extreme tenderness and fever may be the only symptoms of scurvy. When no teeth are present, the hemorrhagic changes in the gums are absent. Swelling of the extremities may also be absent. An early sign of scurvy, which is often overlooked, is hematuria. Roentgen examination may be negative, in fact, the changes in the roentgenogram may not be positive until a month or more following the time at which treatment was initiated.

It has recently been found that the cevitic acid (ascorbic) acid content of the blood serum and urine are quite low in scurvy. Such a test might aid in the diagnosis of a case similar to that here under consideration. The rapidity with which the tenderness and fever of an active scurvy disappear following the administration of vitamin C is well known and could well fit in with the case in question.

VAN SLYKE TEST

To the Editor—What is the significance of the Van Slyke test? How is the test made? Can a blood specimen be sent to the laboratory for the test or is it necessary that the patient present himself to the technician? Please omit name.

M D, Florida

ANSWER—The Van Slyke test is a method employed for the determination of the alkali reserve of the blood plasma, often called the carbon dioxide combining power of the blood plasma. This is the most important test for the detection of acidosis or alkalosis. It should be done in every case of suspected acidosis, including severe diabetes, nephritis and ketosis.

The principle of the test is the determination of the carbon dioxide content of blood plasma. The blood plasma is shaken in a separatory funnel filled with an air mixture the carbon dioxide tension of which approximates that of normal arterial blood. Thus the plasma combines with as much carbon dioxide as it is able to hold under normal tension. A known volume of the saturated plasma is then run into a special apparatus,

acid is added, and carbon dioxide is liberated by the production of a partial vacuum. The carbon dioxide is measured at atmospheric pressure and the volume corresponding to 100 cc. of plasma is calculated. A special expensive Van Slyke manometric apparatus is required for this test.

Another method consists of titrating the bicarbonate content of the plasma. It is given in Osgood and Haskins, *Laboratory Diagnosis*, 1931, on pages 296 to 298. It is too long and complicated to give in detail here. The titration method of Van Slyke as modified by Haskins and Osgood agrees closely with the figure obtained by the gasometric method.

The patient must present himself to the technician at the laboratory. Special precautions are necessary in drawing the blood. The patient should rest for one hour. One drop of potassium oxalate, saturated solution, is placed in a small test tube, 5 cc. of venous blood is obtained and the tube is inverted to mix with the oxalate. The blood must be kept in a cool place and the test done within two or three hours.

ANAL NEUROSIS

To the Editor—What is the pathologic condition underlying anal neurosis? I can detect no anal, rectal or adjacent organic disease. The patient does not have hemorrhoids, fissure, fistula, cryptitis, papillitis or pectinitis, but he continuously complains of a burning scalding pain from the sphincter outward on the right side of the anus. He has been treated for years by rectal quacks and regular doctors. The regular doctors have done no more good than the quacks. Will cutting the presacral nerve relieve the anal discomfort? He had a thorough alcohol injection six months ago.

M D, Oklahoma

ANSWER—It is usually unwise to speculate as to the cause or nature of an anorectal disorder on the basis of its description alone. However, if the patient developed his troublesome symptom following the onset of the treatment mentioned it is probable that the difficulty may be traced to that. Probably it will not help to cut the presacral nerve, which has its origin in the sympathetic nervous system. The nerves supplying the margins of the anus originate in the sacral roots. It would be unwise to cut these nerves, because the sensory and motor fibers are intimately connected. So-called anal neurosis is usually seen in just such cases as the one described. The difficulty usually originates as one of the prevalent "rectal" complaints, and "anal neurosis" develops after prolonged treatment and many operations.

EFFECTS OF MORPHINE

To the Editor—What would be the effect of one-eighth grain (0.008 Gm.) of morphine sulphate given by mouth to a woman 72 years old sick in bed with chronic myocarditis having at the time a rapid heart of regular rate with an occasional extrasystole complaining of a weak spell and precordial distress and being at the time under considerable nervous apprehension and never having had morphine before by mouth or any other way? How soon after administration by mouth would the effect occur? How would the effect if any, show itself to an objective examination?

M D Rhode Island.

ANSWER—The first effect most likely would be a relief from the distress, a diminution of the ability to fix attention, and the induction of a dreamy state, succeeded by drowsiness, apathy and sleep. Very rarely excitation, extreme restlessness and even delirium occur instead of the phenomena of sedation. Such effects may occur from fifteen to thirty minutes after a dose taken by mouth, although they may not appear for hours if conditions for absorption from the alimentary tract are unfavorable. Objective examination, when the effects are at their height, would show small pupils, a diminution of the pulse and of the respiration rate. Constipation is usual, nausea and even vomiting are not uncommon after-effects.

RADIATION AND WATER METABOLISM IN EPILEPSY

To the Editor—Is there any information available as to the effects of roentgen irradiation of the pituitary on the water metabolism especially in epilepsy?

HUGH MACDONALD M D Evanston Ill

ANSWER—In the literature there is no evidence available as to the effects of roentgen irradiation of the pituitary on water metabolism especially in epilepsy. However, an authority on epilepsy reports that he has tried this in a few cases without being able to convince himself that radiation under such circumstances has any definite effect on water metabolism. This authority feels that radiation gives collective results on the pituitary hormones without a specific effect on the particular hormone concerned. In a broad way his conclusion is that no beneficial effect can be demonstrated by high voltage roent-

gen therapy applied to the pituitary in cases of epilepsy. A second authority said that he had made special efforts to get information on this subject but without success. In general, at present, the tendency to irradiate the pituitary in a great variety of disturbances, glandular and otherwise, should be deprecated. Not only does roentgen radiation produce an indeterminate change in the pituitary itself, which may have far reaching consequences, but parts of the central nervous system are exposed to the rays at the same time.

INTRANASAL IMMUNIZATION OF SCARLET FEVER

To the Editor—Will you please send me the technic of intranasal immunization of scarlet fever?

W K BULLOCK M.D, Vernal Utah.

ANSWER—Various methods have been employed in attempts at intranasal immunization against scarlet fever. The toxin may be sprayed or instilled into the nose. The amounts of toxin employed for a single treatment have ranged from 2 or 3 to 10 cc. The treatments have been given at intervals of twenty-four hours to one week by different workers. Most of the toxin introduced into the nose is eventually swallowed. It has been shown that partial or complete immunity results from administration of toxin by mouth. Neither method is as effective as hypodermic injection.

'THE POLARITY OF CHEST LEADS

To the Editor—Will you accord me the privilege of commenting on your answer to my letter of August 25 (*Queries and Minor Notes*, *THE JOURNAL*, November 16 p 1627) in regard to the polarity of chest leads? Also I should like to add another argument for my view as to the preferable polarity.

I will not debate the first paragraph of your answer but will merely remark that the incongruity of the inverted record offends my taste but chacun à son goût.

The second paragraph of your answer is I think, a quite inadequate solution of the difficulty discussed. There is a definite need for a general designation for each component of the group of initial ventricular deflections in chest leads as in limb leads. For instance I am at present writing a paper on a matter relating to precordial leads and I wish to refer to the frequent absence of the large initial ventricular deflection in cases of anterior infarction. I should like to write 'R is frequently absent, but this term is not applicable to inverted records while to call the deflection a Q wave is highly objectionable. What term can be used for the missing deflection? McGinn and White's idea is excellent for describing the initial deflections of a particular record but obviously it furnishes no basis for terms of general applicability.

There is however another more fundamental argument I omitted it from my former communication for the sake of brevity, but I will state it here as compactly as possible.

If the derivation is made from one point on the precordium and another point on a limb, the electrocardiogram is essentially a record of the rather large changes in potential at the precordial electrode for the potentials at the distant electrode are relatively small. We are dealing in fact, with a semidirect lead from the surface of the heart and the potentials recorded are largely determined by the potentials in that part of the heart immediately underlying the precordial electrode. The average electric vector of the whole heart has little influence in this case.

The possibility of thus recording local electrical phenomena in the heart has stimulated interest in the exploration of the whole precordial surface and observations are being extended even to the posterior surface of the heart through the esophagus. The pattern of the deflections obtained from these different points varies widely those from the esophagus being more or less the inverse of those from the anterior surface. In view of the variety of patterns recorded it is certain that much confusion will result unless a sound principle guides the choice of polarity.

There is no doubt about what this principle should be. The requirement is that the records should show unequivocally the sign of the potential developed in the part of the heart under examination, and we must agree whether positive potentials are to be represented by upward or by downward deflections. Now the normal initial ventricular deflection is caused by a positive potential at the precordial electrode, since the underlying myocardium is invaded from within outward but if the inverse polarity is used, the deflection is made downward. It seems to me confusing and unwise to choose a downward deflection to indicate a positive potential. To do so violates a long established convention by which positive quantities are always represented by ordinates above the horizontal axis.

The normal polarity moreover gives records that are consistent with the records made by limb leads in particular by lead 2. The erect R of lead 2 means that the left leg electrode is positive during the early phase of the spread of ventricular excitation. Now the left leg potential is influenced chiefly by the state of the surface of the apical half of the heart and an electrode on the precordium over the apex is affected in the same sense. It is therefore consistent that the deflection representing the initial potential on the precordium should be in the same direction as the deflection representing the initial left leg potential that is that it should be upward.

FREDERICK H HOWARD, M.D New York.

Medical Examinations and Licensure

COMING EXAMINATIONS

AMERICAN BOARD OF DERMATOLOGY AND SYPHILOLOGY Written examination for Group B applicants will be held in various cities throughout the country March 14. Oral examination for Group A and B applicants will be held in Kansas City Mo. May 11-12. Applications for written examination should be filed with the secretary before Jan. 15. Sec., Dr. C. Guy Lane, 416 Marlboro St. Boston.

AMERICAN BOARD OF OBSTETRICS AND GYNECOLOGY Written examination and review of case histories of Group B applicants will be held in various cities of the United States and Canada, Dec. 7. Sec. Dr. Paul Titus, 1015 Highland Bldg. Pittsburgh (6).

AMERICAN BOARD OF OPHTHALMOLOGY Kansas City Mo. May 11. Asst. Sec., Dr. Thomas D. Allen, 122 S. Michigan Ave. Chicago.

AMERICAN BOARD OF ORTHOPAEDIC SURGERY St. Louis Jan. 11. Sec., Dr. Fremont A. Chandler, 180 N. Michigan Ave. Chicago.

AMERICAN BOARD OF OTOLARYNGOLOGY Kansas City, Mo. May 9. Sec. Dr. W. P. Wherry, 1500 Medical Arts Bldg. Omaha.

AMERICAN BOARD OF PSYCHIATRY AND NEUROLOGY New York, Dec. 30. Sec. Dr. Walter Freeman, 1726 Eye St. N. W. Washington D. C.

ARIZONA Basic Science Tucson Dec. 17. Sec. Dr. Robert L. Nugent, Science Hall University of Arizona, Tucson.

CALIFORNIA Reciprocity Los Angeles Dec. 4. Sec. Dr. Charles B. Pinkham, 420 State Office Bldg., Sacramento.

COLORADO Denver, Jan. 7. Sec. Dr. Harvey W. Snyder, 422 State Office Bldg. Denver.

KANSAS Topeka Dec. 10-11. Sec. Board of Medical Registration and Examination Dr. C. H. Ewing, 609 Broadway. Larned.

KENTUCKY Louisville, Dec. 3. Sec. Department of Health Dr. A. T. McCormack, 532 W. Main St. Louisville.

MARYLAND Medical (Regular) Baltimore, Dec. 10-13. Sec. Dr. John T. O'Mara, 1211 Cathedral St. Baltimore. *Medical (Homeopathic)* Baltimore Dec. 10-11. Sec. Dr. John A. Evans, 612 W. 40th St. Baltimore.

MINNESOTA Basic Science Minneapolis Jan. 7-8. Sec. Dr. J. C. McKinley, 126 Millard Hall University of Minnesota, Minneapolis.

Illinois June Examination

Mr. Homer J. Byrd, superintendent of registration, Illinois Department of Registration and Education, reports the written and practical examination held at Chicago, June 25-29, 1935. The examination covered 10 subjects and included 100 questions. An average of 75 per cent was required to pass. Two hundred and sixty-one candidates were examined, 259 of whom passed and 2 failed. The following schools were represented:

Oklahoma June Examination

Dr. James D. Osborn Jr., secretary, Oklahoma State Board of Medical Examiners, reports the written examination held in Oklahoma City, June 5-6, 1935. The examination covered 12 subjects and included 120 questions. An average of 75 per cent was required to pass. Fifty-two candidates were examined, all of whom passed. Four physicians were licensed by reciprocity. The following schools were represented:

| School | PASSED | Year Grad | Per Cent |
|---|-------------------------|-----------|------------------|

Montana October Examination

Dr. S. A. Cooney, secretary, Montana State Board of Medical Examiners, reports the written examination held in Helena, Oct. 1-2, 1935. The examination covered 10 subjects and included 50 questions. An average of 75 per cent was required to pass. Four candidates were examined, all of whom passed. Seven physicians were licensed by reciprocity and two physicians were licensed by endorsement after an oral examination. The following schools were represented:

The Pneumonokonioses (Silicosis) Literature and Laws of 1934
International Abstracts Extracts and Reviews of the Pneumonokonioses
and Their Associated Diseases and Subjects By George G Davis M.D.
Associate Clinical Professor of Surgery Rush Medical College University
of Chicago Ella M Salmonsens Medical Reference Librarian the John
Cramer Library Chicago and Joseph L Earlywine Attorney at Law
Chicago Cloth Price \$10 Pp 490 Chicago Chicago Medical
Press 1935

In 1934 the authors, using a similar title, presented through citations essentially all the bibliography of dusty lung diseases, beginning with 1556 and ending with 1933. That volume included the laws of the various states with reference to dusty disorders of the lung. In it the forecast was made that it constituted the first volume of a series. The present publication is the second volume of this series. Its chief contents are limited to publications on dusty lung diseases and closely related subjects solely for the year 1934. The principal difference in the two volumes resides in the fact that in the present publication abstracts, extracts or reviews are furnished—at times in great length—so that from this one publication it is possible to grasp the trend of thought of workers throughout the world with respect to the many onerous problems associated with dusty lung diseases—their causes, diagnosis, prognosis, significance and compensation. All the references in this volume have been translated into English. On first examination of this book it appears from alphabetical arrangements that the material is poorly organized. However, through the use of secondary indexes it readily becomes possible to bring together quickly all the scattered publications, such as those on "asbestos," "dust counts" or "fibrosis." Part II of the present volume, entitled "Laws—States and Cases," constitutes a supplement to the original publication, and without association with the original publication is by no means complete. This portion of this book is limited to sixteen pages and embraces only a small amount of legal material specifically associated with dusty lung diseases. As to this dearth of material no complaint can be made against the authors, and obviously it is the result of limited legislative action in this domain and of few basic decisions of the supreme courts of the several states. This book is by no means to be regarded as a textbook of dusty lung diseases. It is, as its title implies, a compilation of the extensive literature (396 items) published in the year 1934. For industrial hygienists, industrial physicians, and attorneys engaged in medicolegal practice, it will prove to be of much practical worth. Its greatest worth will fall to those users who have available the preceding volume containing the fundamental publications on this topic and the details of such laws as have a bearing on this type of occupational disease.

Radiological Atlas of Chronic Rheumatic Arthritis (The Hand) By
S Gilbert Scott M.R.C.S. L.R.C.P. D.M.R. and E. Honorary Radiologist
to the British Red Cross Clinic for Rheumatic Diseases Regent's Park
Cloth Price \$8.75 Pp 76 with 42 illustrations New York &
London Oxford University Press 1935

This atlas describes in detail the characteristic changes encountered in the hand in each of the four groups of rheumatoid hypertrophic, chronic infective and gouty arthritis. The author chose the hand because he agrees with Schober, who said "the hand is the visiting card of the rheumatic patient." The radiologic examination should play an important part in the diagnosis and classification of arthritis. In a certain number of cases it is possible to form a fairly accurate idea as to the prognosis. The examination of a large number of standardized roentgenograms of the hand at all ages leads one to conclude that "a man is as old as his bones" rather than "as old as his arteries."

Roentgenology portrays pathologic changes on the films in terms of shadows, and it is on the correct interpretation of these shadows that the ultimate value of the examination depends, while the experience gained by investigating a large amount of roentgenologic material is essential for attaining the maximum degree of diagnostic skill. The most frequent mistake is to diagnose symptoms that are being caused by malignant disease (usually secondary carcinoma of the vertebrae or bones of the pelvis) as lumbago or sciatica. The next mistake is to take in order of frequency is the diagnosis of Paget's disease or osteitis deformans. If the possibility of error in diagnosis is to be reduced to the minimum, every patient complaining of persistent rheumatic pains should be subjected to a careful roentgen examination.

Decalcification of the skeleton is peculiar to rheumatoid arthritis. Loss of cartilage with the formation of osteophytes is associated with the osteoarthritic group. Loss of cartilage with early sclerosis of those bones entering into the formation of the joint, usually of a single finger, denotes a chronic infective arthritis, while the "punched out" areas seen on the edge of the articular surfaces indicates the presence of deposits, which are characteristic of gouty arthritis. It is possible to have a mixed arthritis present in the same patient. In fact, the three types of arthritis might be represented in a single roentgenogram of one hand.

The degree of activity of the arthritis can be estimated in several of the groups from the roentgen examination. For example, the more transparent the bones in rheumatoid arthritis, the more active is the disease. Loss of cartilage in a single finger joint without sclerosis of the bone around denotes an active infective arthritis, and this evidence of activity or quiescence of the condition can be used to estimate the effect of any particular method of treatment. The general decalcification associated with rheumatoid arthritis takes place without any alteration in bone structure and suggests the possibility of a metabolic origin of rheumatoid arthritis.

The author discusses the term "bone density balance." A definite study of the more intimate structure, for instance, of the third metacarpal bone, will demonstrate the presence of three grades of density. The density of bone and any deviation from the normal cannot be accurately assessed unless certain technical details are observed having for their object the production of roentgenograms identical in quality. A roentgenogram of the bone is essential for the study of chronic rheumatic arthritis, not only for comparative purposes but as being the only reliable means of detecting the early decalcification of bone associated with rheumatoid arthritis.

In rheumatoid arthritis the principal clinical feature, atrophy of the soft tissues, is registered roentgenographically in the bones not as a true atrophy but as a general decalcification. Decalcification of bone may occur a considerable time before the onset of joint symptoms and arthritic changes show themselves only when the cartilage has become involved in the general atrophy of tissue. The author believes that no case should be diagnosed or classified as rheumatoid arthritis unless a generalized decalcification of bone is present.

In rheumatoid arthritis the stages as indicated roentgenographically are: First stage, decalcification of bone. Second stage, loss of cartilage in several of the minor joints, increase of decalcification. Third stage, erosion of articular surfaces, subluxation, increase in decalcification. The disease may become quiescent at any time. This will be denoted by a return of bone calcium and an increase in bone density.

In hypertrophic arthritis the stages as indicated roentgenographically are: First stage, loss of cartilage, usually to one side of the terminal joint of a finger, slight lateral displacement. Second stage, complete loss of cartilage with the formation of osteophytes, Heberden's nodes, or the deposit of periarticular ossicles in close proximity of a joint. Third stage, irregularity of the joint surfaces, excessive osteophytic formation.

In chronic infective arthritis the stages as indicated roentgenographically are: First stage, loss of cartilage in a single joint, wrist or metatarsophalangeal joints of ring or middle finger usually involved. Second stage, sclerosis of bone in the immediate neighborhood. Third stage, bony ankylosis, subluxation.

In gouty arthritis the characteristic roentgenographic feature is the presence of deposits, which are recorded on the film as small "punched out" areas on the surface of the articular bone, immediately under the cartilage, or show as definite holes in the articular end of the bone. Critical examination of a roentgenogram of gouty arthritis may show even an earlier stage, indeed the first, which is often overlooked. This consists of a small local destruction or a "wiping out" of bone trabeculae in the immediate neighborhood of a joint and precedes the actual formation of the deposit. The changes may require the use of a lens for their detection.

In gouty arthritis the stages as indicated roentgenographically are: First stage, minute localized destruction or disappearance of bone trabeculae in the immediate neighborhood of a joint. Second stage, small "punched out" areas on the surface of the articular bone, or holes in the articular end of the bone, loss of cartilage may be present. Third stage, loss of cartilage in those joints in which deposits are demonstrated. Fourth stage, destruction of the articular ends of bones from excessive gouty deposits. In gouty arthritis there is no alteration in bone density, however advanced the disease may be.

This is an interesting and instructive contribution. The author has commendably crystallized much material. A word of praise is also due the publishers. It is to be regretted that so fine a book should have the limited sale imposed on it by the price.

Baptism of the Infant and the Fetus. An Outline for the Use of Doctors and Nurses. By the Reverend J. R. Bowen, Chaplain St. Joseph Mercy Hospital, Dubuque, Iowa. Paper. Price 25 cents. Pp. 11. Dubuque: M. J. Knippel Company, 1935.

This brief outline prescribes methods of baptizing Catholic babies. It is directed to Catholic and non-Catholic physicians and nurses officiating at deliveries with the view of bringing "the privileges of Baptism to the little ones, and affording inestimable consolation to the parents," particularly when viability of the new born is in question. This urgency is discussed under such special headings as conditional baptism, the premature fetus, difficult delivery, baptism in the uterus, when a pregnant mother is dying, when a mother dies in pregnancy, the baptism of monsters, and disposal of the dead fetus. Due respect is paid to medical and moral considerations illustrated in the conditions for performing a cesarean section after the death of the pregnant mother. It is made perfectly plain that "a dying mother is in no condition to ponder such an obligation" as permitting a section. Furthermore, section is not permitted when it "does not offer a chance of saving the mother's life but, on the contrary, will directly contribute to her death." The material is clear and brief, and the suggestions should prove no burden to conscientious physicians and nurses of any creed. The pamphlet lends itself to ready reference and should be available in all maternity departments. It is published under official Catholic auspices.

Nouveau traité de médecine. Publié sous la direction de G. H. Roger Fernand Vidal et P. J. Teissier. Fascicule XX. Pathologie du système nerveux (bulbe, nerfs crâniens, méninges, moelle). Half cloth. Price 130 francs. Pp. 984 with 193 illustrations. Paris: Masson & Cie, 1935.

For years those who have the other volumes of this series dealing with the nervous system have been awaiting the publication of the present one. It is five years since the last of the other volumes dealing with the nervous system in this series was published and ten since the first. The subjects already covered are the cerebrum and cerebellum, the sympathetic nervous system and the neuroses, and there is a volume on the general symptomatology of the nervous system. The present volume treats of the pathology of the brain stem, the cord, the cranial nerves and the meninges. The treatment is orderly and follows a conventional pattern, each brain stem subdivision being taken up by a different author, Lari and Thiers contribute most of the articles dealing with the pathology of the spinal cord. The authors of all the sections are well recognized in their respective fields in French neurology. When one goes over each of the topics it is amazing to note the thoroughness with which the subject is discussed, being detailed without waste of words. For the most part the anat-

omy and physiology are given in sufficient detail to permit understanding of the pathology, and in a number of places there is even a historical discussion of the development of knowledge concerning the type of disorder studied. The book is fairly well illustrated with pictures of patients, reproductions of x-ray plates, and microscopic sections. It should serve as a good reference book for persons deeply interested in neurology who do not have the courage or the knowledge of German to consult Lewandowsky, and it must not be forgotten that the present French reference book is more nearly down to date than that famous one in German. Since the various parts are discussed by different authors the style varies, but on the whole it is fairly easy French reading.

Kleine Chirurgie. Von Professor Dr. Hans Kurtzahn. Third edition. Paper. Price 12 marks. Pp. 456 with 170 illustrations. Berlin & Vienna: Urban & Schwarzenberg, 1935.

This manual of minor surgery is intended primarily for the use of medical students, for which purpose it is admirably adapted. It reflects the manner in which the author has anticipated the need of students well established and easily performed procedures are given preference to those still in the experimental stage. The organization of the material resembles that of most textbooks of similar character. The book is extensively illustrated and has an adequate index. The tannic acid treatment of burns is not mentioned. Ethyl chloride, not popular in this country for general anesthesia, is recommended for this purpose. An alcoholic solution of tannic acid for preparation of the operative field does not have many sponsors here. Such remarks are not intended to diminish the merits of the book, they only illustrate the confusion created in the mind of an inexperienced American student who finds in foreign books statements not conforming with instructions received in our schools. While the manual summarizes in a practical manner the principles of minor surgery for a medical student, it is too concise, primitive and superficial to be of great service to a general practitioner.

1000 Questions and Answers on T. B. Edited by Fred H. Helse, M.D. Medical Director, Trudeau Sanatorium. Cloth. Pp. 232. New York: National Tuberculosis Association, 1935.

Undertaking to answer a thousand questions about tuberculosis is a momentous task. It would scarcely be expected that such a book of questions and answers would meet with universal approval among physicians dealing extensively with tuberculosis. Difficulties inherent in the question and answer technique are in many instances almost insurmountable. The questions have been assembled from a question and answer department of the *Journal of the Outdoor Life* and here published. Even physicians who do not wholly agree with all the answers will nevertheless find that the book should be helpful and encouraging to the tuberculous patient who has practically never been able to ask his doctor all the questions he would like to. The questions are grouped under sixteen different headings and a satisfactory index affords a quick reference to the particular phase of tuberculosis discussed.

Leistung und Grenzen des Röntgenverfahrens bei der Erkennung tuberkulöser Lungenveränderungen. Von Priv.-Doz. Dr. Walter Schmidt, Direktor u. leit. Arzt des Tuberkulosekrankenhauses Heidelberg-Rohrbach. Eine vergleichende röntgenologische klinische und anatomische Betrachtung unter Mitwirkung von Priv.-Doz. Dr. H. Wurm, Prosektor am pathol. Inst. Heidelberg. Nr. 57. Tuberkulose Bibliothek. Beihefte zur Zeitschrift für Tuberkulose. Herausgegeben von Dr. Franz Redeker, Oberregierungs- und Medizinalrat, Berlin, und Dr. Karl Diehl, dirigierender Arzt, Sommerfeld. Boards. Price 10 marks. Pp. 80 with 104 illustrations. Leipzig: Johann Ambrosius Barth, 1935.

This treatise is the fifty-seventh of a series of monographs issued as supplements to the *Zeitschrift für Tuberkulose* and is devoted to a consideration of the value and limitations of roentgenology in the diagnosis of pulmonary tuberculosis as revealed not only by serial x-ray studies but also by correlating the shadows noted on chest films with the pathologic changes disclosed by frontal sections of the lungs. The twenty-six pages of text included in the monograph present excellent discussions dealing with the roentgenologic identification of calcified and noncalcified old (primary?) foci of disease, the early nodule and the early infiltration of pulmonary tuberculosis of the adult type, the possibility of roentgenographically identi-

fying the pathologic condition present, the prognosis, extent and course of the disease, the technic of roentgen examinations and other pertinent topics of importance. The illustrations have been selected with great care and show all desired details distinctly. This splendid, concise and scholarly treatise reflects comprehensive scientific knowledge and extensive clinical experience on the part of the authors and merits the attention of roentgenologists, physicians, investigators and others interested in tuberculosis.

The Anatomy of the Nervous System from the Standpoint of Development and Function. By Stephen Walter Ranson, M.D. Ph.D. Professor of Neurology and Director of the Neurological Institute Northwestern University Medical School Chicago. Fifth edition. Cloth. Price, \$6.50. Pp 501 with 381 illustrations. Philadelphia & London W B Saunders Company 1935.

The fifth edition of this standard textbook differs from the fourth notably by the addition of forty illustrations of brain sections, chiefly from Jacobsohn and Jørgensen, so that the atlas at the end of the text now comprises Weigert sections of twenty transverse levels of the brain stem, five oblique sections through the region of transition between the midbrain and the thalamus, three horizontal sections of the internal capsule, and twelve frontal sections of the cerebral hemisphere. These, with accompanying descriptions, give the elementary student the necessary landmarks for orientation in the study of his laboratory material. The text has been revised without enlargement, with a judicious selection of references to recent research. Limitations of space are doubtless responsible for the omission of much new detail, especially in the cerebral hemispheres, to which one would expect reference. It is unfortunate that in this revision figure 7 (the Kollmann 24 mm human embryo, figure 13 of the fourth edition) is not replaced by a more accurate picture free from the artefacts of that specimen. On the whole the treatment is well balanced, and this work maintains its place as the most generally useful textbook of neuro-anatomy in the English language for medical students.

Laboratory Manual of the Department of Bacteriology and Immunology Peiping Union Medical College. Prepared under the direction of C E Lim Head of Department. Second edition. Cloth. Price \$1.50. Pp 100 with 2 illustrations. Peiping The College 1935.

This manual was designed for service as a practical guide to those diagnostic and analytic laboratory methods in clinical bacteriology and serology which the author has found to be best adapted to the teaching, research and clinical needs of his department. It is free from the objectionable restrictions and divisions that limit the utility, for advanced workers, of manuals written solely for student courses. The material covered is so treated that it is especially useful to those interested in clinical laboratory procedures. Although it lacks illustrations and is too brief for much research use above that for which it was intended, this manual contains useful information not usually found except in comprehensive volumes. The section on laboratory animals is well written and useful, since this subject is usually neglected elsewhere. A table of temperatures, pulse and respiration rates and Scarborough's hematologic chart for normal laboratory animals are included. Procedures are simplified, although frequently more highly modified than necessary for American use. The volume is well outlined and information is easily accessible. References are numerous, a section on classified references is included. A chapter is reserved for the examination of pathogenic fungi.

The Achievement of Happiness. By Boris Sokoloff M.D. Sc.D. Cloth. Price \$2.25. Pp 271. New York Simon & Schuster 1935.

The evaluation of this book is rather difficult because of its unusual nature. Intended as a book of inspiration, it tries to carry out its purpose by means of short lectures consisting of illustrative yarns from the author's experience and also some which he retells at second hand. How much inspiration a depressed psychotic or maladjusted individual can obtain from a literary source is questionable, but, placed in the hands of an occasional chronic complainer, the present work might serve some purpose. The medical information in it is scattered, from various sources, and scanty. The medical topics are chiefly endocrinology, fatigue and sexual adjustment. The author's primary interest, according to the publishers' note, is biochemistry. He does not mention enough of this in the book to

indicate his soundness or unsoundness in this field—he is obviously no psychiatrist. The book need not be wholly condemned for, as a short unsystematized, well written autobiographical scrap-book, it makes interesting reading. The author has apparently had many unusual experiences.

Trattato di micopatologia umana. Diretto dal Prof. Gino Pollacci direttore del r. Laboratorio crittogamico Italiano Pavia. Volume IV. Repertorio sistematico dei miceti dell'uomo e degli animali. Dal Prof. Arturo Nannizzi libero docente di micologia nella r. Università di Siena. Paper. Price 100 lire. Pp 537 with 224 illustrations. Siena S. A. Poligrafica Meini 1934.

In this abundantly illustrated catalogue the diagnosis of each species is given in telegraphic style, making it unnecessary to wade through the Italian verbiage. In addition, a short paragraph indicates the habitat of the fungus and the type of disease produced. Considering the completeness of the catalogue, Nannizzi has done well to keep such an enormous mass of information within the scope of the 557 pages. The subject matter is down to date and in view of its completeness fills a long needed want for a place to go when examining the various fungous species once the mycologist has gotten as far as the generic diagnosis. For English speaking workers the fact that the text is in Italian may be a disadvantage, however, the general sense of the message may be rather readily obtained by the mycologist by piecing together his knowledge of Latin with already established technical terms in mycology. The most serious criticism is the lack of references, but perhaps these indefatigable workers at Pavia and Siena have plans whereby this can be taken care of. This criticism, however, is insignificant in the face of the numerous other valuable features of the catalogue.

The Evaluation of Symptoms Offered After Fifty Years in Medicine. By Oliver T. Osborne M.A. M.D. F.A.C.P. Cloth. Price \$3.50. Pp 163. New Haven Connecticut Yale University Press for the Author 1935.

This is a small book but it contains a tremendous amount of information. No one but a man of great experience could have attempted to gather together symptoms in the manner in which Dr. Osborne has done. One might anticipate that such a condensed array might be uninteresting reading, but this is not the case. This book certainly presents to the practitioner the importance of the symptomatology of disease. "It is the treatment of symptoms that gives success to many physicians who do not even attempt to make a diagnosis." Dr. Osborne, of course, believes in making a diagnosis but wisely places an analysis of symptoms in the first order of importance. The book should be a valuable addition to the library of physicians as well as fourth year medical students.

Puerperal Gynecology. By J. L. Buhl M.D. F.A.C.S. Consultant in Obstetrics Gynecologist Mt. Sinai Hospital Cleveland Ohio. Cloth. Price \$3.50. Pp 199 with 81 illustrations. Baltimore William Wood & Company 1935.

This book provides one with a collection of material that has never before been available in a single volume. The author considers the subject from the onset of pregnancy to the end of the puerperal period stressing in particular antepartum prophylaxis of the more common and sometimes serious results of negligence or careless handling of the patient during the antepartum and delivery periods. The chapter dealing with the pathology of the cervix is well done and should be of great value to the general practitioner doing obstetric work. Although one may not entirely agree with the author as to the feasibility of doing major plastic repair work on the female genital tract immediately following delivery, one can be safely guided by the criteria laid down in the text for the choice of case in which such treatment may be attempted. This book has a definite place in the obstetric field because of the lack of such material calling to the attention of the profession the need for proper surgical care during the early puerperal period.

The Sinister Shepherd. A Translation of Girolamo Fracastoro's Syphilidis sive de morbo gallico libri tres. By William Van Wyck. Cloth. Price \$4.50. Pp 85 with illustrations. Los Angeles Primavera Press 1934.

Here is another translation of the famous discussion of syphilis by Fracastoro. It is handsomely printed and illustrated with reproductions from early editions of this notable work.

Medicolegal

Workmen's Compensation Acts Pneumothorax Not Attributable to Strain.—The claimant, in the course of his work, was on his knees, in a "twisted" position, in a small space, trying to lift one end of a heavy desk. As he made the effort he felt a sharp pain in the left side of his chest, as if something "gave way." The incident was immediately reported to his superior and he was relieved of the task in which he was engaged. Apparently no further symptoms developed for about twenty-four hours and then, while stooping over and cleaning a wash basin, the claimant felt a very sharp pain, so acute that he could not straighten up. He continued to suffer and after about four days was sent to a hospital. After his discharge he instituted proceedings under the workmen's compensation act. The industrial accident commission denied his claim for compensation, and he petitioned the district court of appeal, second district, division 2, California, for a writ of review. That court was of opinion that the claimant was entitled to compensation and therefore annulled the order of the industrial accident commission and remanded the case to the commission for action in accordance with the court's opinion. *Quigley v Industrial Accident Commission*, 35 P (2d) 544. The commission again denied compensation, and the claimant appealed to the Supreme Court of California.

In the words of the Supreme Court, the claimant sustained "a spontaneous hemopneumothorax, that is, a complete collapse of the left lung." The only disputed question, said the court, is whether the collapse of the lung resulted from a preexisting pathologic condition not connected with the employment or from the strain of lifting the desk. Only under the latter condition would the injury be compensable.

The insurance carrier, in opposing the employee's claim for compensation, produced as a witness a specialist in lung diseases who had personally observed probably 225 cases of pneumothorax. In his opinion, he testified, there is always a pathologic condition preceding a spontaneous pneumothorax, whether that condition is demonstrable or not. He had never known spontaneous pneumothorax to develop in a patient whose lungs were normal and healthy. Statistics show that 90 per cent of such cases are due to tuberculosis. Practically all cases of spontaneous pneumothorax develop from a ruptured tubercle on the outer surface of the lung, the rupture of a single tubercle being able to produce the condition without much infection being present. The fact that the claimant spit up blood while he was in the hospital was suggestive of "some pathology." Most cases of pneumothorax, according to the witness, occur while the patient is asleep or at rest. No case of pneumothorax, according to the witness, ever occurred from strain. It was impossible to say whether the condition occurred when the claimant was endeavoring to lift the desk but even if it did, witness believed that the strain of lifting did not cause it. Human lungs are constructed to withstand, without damage, far more pressure than it is possible for a person to build up by physical effort. A scientific conclusion could not be drawn that the effort that the claimant made to move the desk increased the air pressure to such an extent as to cause his pneumothorax. The witness testified that he made a physical examination of the claimant some months after the injury and had examined the roentgenograms taken when the claimant was first in the hospital and had examined also the reports of various physicians. He could not tell definitely, however, whether the claimant had had tuberculosis, although there were some indications that he did have it.

Other medical witnesses testified that they were unable to connect the claimant's pneumothorax with his muscular strain in undertaking to lift the desk, being inclined to connect it rather with an old or an active tuberculosis. One of them called attention to the twenty-four hour period elapsing after that effort and before the onset of disabling symptoms, for which intervening period he could find no adequate explanation if the pneumothorax came on at the time of the strain.

The evidence, said the Supreme Court, amply supports the action of the industrial accident commission in disallowing

compensation. Physicians testifying for the employee gave a logical explanation of the cause of the delay in the appearance of symptoms and testified that the strain caused a tear in the lung tissue that led to the collapse of the lung and that they could find no evidence of tuberculosis. This evidence was directly contrary to the evidence introduced on behalf of the insurance carrier. It was beyond the province of the appellate court, however, to weigh the evidence.

The action of the commission in disallowing compensation was affirmed.—*Quigley v Industrial Accident Commission (Calif.)*, 43 P (2d) 289.

Charitable Hospitals Liability for Negligence of Student Nurse.—One of the plaintiffs was a patient in the defendant hospital. While there she was severely burned by a hot water bottle, negligently left in a bed that a student nurse prepared for her reception immediately after an operation. The injured patient and her husband sued the hospital, and from a judgment in their favor the hospital appealed to the Supreme Court of Washington.

Under the established rule in the state of Washington the hospital, a charitable institution, was not liable for the negligent act of an employee unless it failed to exercise ordinary care in selecting and retaining her. The trial court however, instructed the jury that the negligence of the nurse in this case raised a presumption that the hospital had not exercised ordinary care in her selection and retention, thus applying to the situation the rule of *res ipsa loquitur*. In the opinion of the Supreme Court, this was error, the nurse's negligence did not necessarily raise any such presumption. It would not be reasonable or logical to attach to a single negligent act of an employee the presumption that her employer was negligent in her employment. To apply the rule of *res ipsa loquitur* in such cases would deprive charitable institutions of the benefit of the rule of exemption and in effect make them liable generally for the negligence of their employees. The Supreme Court reversed the judgment of the trial court and remanded the case for a new trial.—*Bise v St Luke's Hospital (Wash.)*, 43 P (2d) 4.

Diseases Constitutionality of Illinois Occupational Disease Act.—Section 1 of the Illinois occupational disease act, enacted in 1911, provides:

That every employer of labor in this State, engaged in carrying on any work or process which may produce any illness or disease peculiar to the work or process carried on or which subjects the employees to the danger of illness or disease incident to such work or process to which employees are not ordinarily exposed in other lines of employment shall, for the protection of all employees engaged in such work or process adopt and provide reasonable and approved devices means or methods for the prevention of such industrial or occupational diseases as are incident to such work or process.

The constitutionality of this section was contested in two cases here abstracted. In each case the Supreme Court of Illinois held the section to be unconstitutional.

It is a well recognized requirement, said the Supreme Court, that the terms of a penal statute creating a new offense must be sufficiently explicit to inform those who are subject to it what conduct on their part will render them liable to its penalties. *Connally v General Construction Co.*, 269 U S 385, 46 S Ct 126. The fact that the act has been construed and applied during a long period of time does not necessarily make it valid and render it immune from attack. Section 1 of the act under consideration imposes a duty on every employer to know not only whether he is engaged in the pursuit of any work or process which may produce a particular illness or disease but also whether such work or process may produce an illness or disease which is peculiar or special thereto. He must know whether the employment subjects his employees to the danger of illness or disease incident to such work or process to which employees are not ordinarily exposed in other lines of employment. He is required to possess accurate information not only as to the etiology of all occupational diseases to which his employees may be subject but also those to which the employees of other employers are subject. The mere statement of the proposition carries its own condemnation, said the court. The act furnishes no guide to an employer seeking to determine whether an illness or disease produced by his employment is one "to which employees are not ordinarily exposed

in other lines of employment" The meaning of the word "ordinarily" as used in this respect is especially ambiguous. It is obviously impossible for any person reading the language to discern with a reasonable degree of certainty to whom it applies or what illness or diseases fall within its general terms.

Furthermore, section 1 does not attempt to state what "devices" the legislative mind contemplated. To be valid the statute must prescribe a standard so definite, fixed and understandable as to permit a compliance therewith by one who desires to meet its requirements. The statute need not specify and particularize the exact norm, but it must lay down a guide that has a definite, fixed meaning. While the word "reasonable" has a fixed definite meaning at common law as applied to a standard of degree and diligence, the word as used in section 1 cannot be given that sense, as it is employed as a description of the "devices, means or methods" commanded to be furnished and adopted by the employer. "Approved," as used in section 1, is not more intelligible than the word "reasonable" as employed in that section. "Approved" has no definite, special, technical, trade or common law meaning or meaning by established precedents. By whom the approval mentioned is to be made is left open to conjecture. From a reading of section 1 the employer must decide whether his industry is included in the class thereby created and whether he must provide the "reasonable and approved devices, means or methods," and what they are, for the prevention of occupational diseases incident to the work of his undertaking. The employer must be able to forecast accurately the devices, means and methods required of him to avoid liability under the statute. It would be unjust to hold the employer liable in the exercise of his business knowledge for his failure to guess correctly as to his duty where the statute itself creates no criteria for his safe and sure guidance. A statute which requires the performance of an act in terms so indefinite, uncertain and puzzling that men of ordinary intelligence must necessarily guess at its meaning and differ as to its application transcends due process of law.—*Parks v Libbey-Owens-Ford Glass Co (Ill)*, 195 N E 616 *Boshuizen v Thompson & Taylor Co (Ill)*, 195 N E 625

Workmen's Compensation Acts Death from Thrombosis of Mesenteric Artery Following Infected Injury of Eye—Barto, the deceased employee, received compensation for the loss of the use of an eye, resulting from an infection of a wound of the eye in the course of his employment. The wound was infected May 27, and the resulting ulcer on the eye was pronounced healed July 16. About seven months after the latter date Barto died, after an abdominal operation three days earlier, but whether there had or had not been any symptoms of illness during that period, the record does not show. The operation disclosed multiple thrombi in the small branches of the mesenteric artery, involving about three feet of the small intestine. No point of origin of this infection was found in the abdomen. Barto's widow, attributing her husband's death to the injury to his eye, sought compensation under the workmen's compensation act. The industrial commission disallowed compensation, the circuit court set aside the order of the commission, and the employer appealed to the Illinois Supreme Court.

The medical experts agreed that death resulted from thrombosis of the mesenteric artery. They agreed also that the thrombosis was caused by an infection existing in some part of the body. No source of infection was found in the abdomen. There was evidence that the deceased employee had pyorrhea at the time of the injury to his eye. There was evidence also that a year before his death he had what seemed to be an infected gallbladder, for which operation was advised but refused by him. There was lay evidence to show that pus was occasionally discharged from the infected eye up to the time of the employee's death, and medical evidence to show that although the ulcer had healed infection might exist and be discharged into the blood stream. No witness testified definitely that the thrombosis resulted from the eye infection, the most any of them would say was that it could have resulted from that source.

The record is clear, said the Supreme Court, that where as in this case, there is more than one possible point of infection, medical experts cannot determine from which source infective

thrombosis arises. Lacking more definite proof of a causal relation between the eye infection and the thrombosis, the circuit court was not warranted in setting aside the order of the industrial commission disallowing compensation. The judgment of the circuit court was therefore reversed and the award set aside.—*Barto v Industrial Commission (Ill)*, 195 N E 454

Malpractice Liability for Death of Patient under Anesthetic—The mere fact that a patient dies under the influence of an anesthetic, said the superior court of Delaware, imposes no liability on a dentist who administers nitrous oxide gas to the patient preparatory to the extraction of a tooth. The doctrine of *res ipsa loquitur* does not apply in such a case. The plaintiff must either allege and prove a lack of requisite knowledge or skill on the part of the defendant or a failure on his part to exercise the proper degree of care and diligence, or, some negligence of the defendant being alleged, there should appear some state of facts connected with the instrumentality in the control of the defendant or with the treatment accorded to the plaintiff which brings about a result so inconsonant with the normal and usual result that it must presuppose negligence in the application of the treatment.—*Mitchell v Atkins (Del)*, 178 A 593

Indemnity Insurance Malpractice by Unlicensed Assistant—The Hartford Accident and Indemnity Company issued to Lee, a licensed osteopath, a malpractice indemnity policy which excluded from coverage injuries caused by Lee or his assistant while engaged in any unlawful act. A patient obtained a judgment against Lee and his assistant, Matson, in an action based on malpractice. Subsequently the patient instituted the present action against the insurance company to recover the amount of the judgment. The trial court held for the defendant, and the plaintiff appealed to the district court of appeal, second district, division 2, California.

Apparently, the unlicensed assistant, Matson, treated the plaintiff. Since the assistant, said the court, was without any license to heal the sick and afflicted in California, his act in the treatment of the plaintiff and the conduct of Lee in knowingly permitting such treatment made them both guilty of a violation of law and the performance of an unlawful act. The plaintiff's injuries were due to the lack of skill exercised by the assistant and were the result of the use by Lee of an unqualified and unlicensed assistant in violation of the provisions of the law. Such being the case, the loss was not covered by the insurance policy. The judgment of the trial court was therefore sustained.—*Glesby v Hartford Accident & Indemnity Co (Calif)* 44 P (2d) 365

Current Medical Literature

AMERICAN

The Association library lends periodicals to Fellows of the Association and to individual subscribers to THE JOURNAL in continental United States and Canada for a period of three days. Periodicals are available from 1925 to date. Requests for issues of earlier date cannot be filled. Requests should be accompanied by stamps to cover postage (6 cents if one and 12 cents if two periodicals are requested). Periodicals published by the American Medical Association are not available for lending but may be supplied on purchase order. Reprints as a rule are the property of authors and can be obtained for permanent possession only from them.

Titles marked with an asterisk (*) are abstracted below

*Gastro-Intestinal Manifestations Accompanying Diseases in Upper Urinary Tract B S Abeshouse Baltimore—p 477

Gastro-Intestinal Symptoms in Diseases of Urinary Tract—According to Abeshouse, an accurate diagnosis of a lesion in the upper urinary tract must be based on a detailed history, careful physical examination, complete laboratory studies of urine and blood, and a thorough urologic study. Every pathologic condition in the kidney and ureter should be studied from the standpoint of its effect not only on the urinary tract but also on the body as a whole. Pathologic conditions in the upper urinary tract usually are accompanied by well recognized symptom complexes but occasionally are unaccompanied by any urinary symptoms. In many instances they produce symptoms referable to other organs or systems of organs outside the urinary tract, particularly the gastro-intestinal tract. The gastro-intestinal manifestations of diseases in the upper urinary tract may be classified as toxic, mechanical or reflex. The renodigestive reflexes concerned in the retroperitoneal syndrome are classified according to their effects on the various portions of the gastro-intestinal tract: the principal types are the renogastric and reno-intestinal reflexes. These reflexes may be motor secretory or vasomotor. They may be associated with one another or combined with cardiac respiratory or vasomotor reflexes, or occur simultaneously with other visceromotor reflexes. The point of origin of the renodigestive reflexes varies in the different clinical cases. The response to these stimuli varies in the same or in different patients. Factors influencing the response to these renodigestive reflexes are summation of primary irritative stimuli sensitization of nerve centers and individual predisposition. The gastro-intestinal manifestations of these renodigestive reflexes may be classified as gastroduodenal, biliary appendical colonic and peritoneal. Cases illustrating each type are presented by the author. A complete urologic examination is indicated in every obscure abdominal condition especially in patients who have been subjected to an abdominal operation without relief. Every urologist should familiarize himself with the symptomatology of pathologic conditions in the gastro-intestinal tract. Every surgeon should recognize the fact that lesions of the upper urinary tract may produce symptoms of a pathologic condition in the gastro-intestinal tract and vice versa. Pyelo ureterography retrograde or intravenous is of immeasurable value in the differential diagnosis of lesions within the upper urinary tract and in their differentiation from other pathologic conditions in the gastro-intestinal tract and in other organs adjacent to the kidneys and ureters. A flat roentgenogram of the genito urinary tract should be adopted as a routine diagnostic measure in every obscure abdominal condition especially in cases of so-called chronic appendicitis. A negative roentgenogram of the genito-urinary tract does not exclude a disease of the kidney or ureter. Pyeloureterographic studies should include horizontal and upright

positions in order to rule out a movable kidney. Stereoscopic pyelo-ureterograms are of great value in determining the exact location and size of any abdominal mass and its relation or effect on the upper urinary tract. The author urges the establishment of an adequate follow-up system to determine the incidence of cures and failures in the operative treatment of abdominal conditions in view of the high percentage of failures to obtain relief of abdominal pain as reported in statistical studies of large series of abdominal operations.

Use of Typhoid Vaccine in Treatment of Chorea—Ash and Einhorn suggest that shock from the use of typhoid vaccine in the treatment of chorea may do harm in the presence of rheumatic carditis. Injections repeated at short intervals may also do harm by causing a continued lowering of the number of circulating leukocytes. Of their seventeen patients having chorea treated with intravenous injections of typhoid vaccine, in four patients with uncomplicated chorea and in one with chorea and rheumatic carditis there occurred a secondary rise of temperature from one to two weeks after the last injection of vaccine. In three patients treated in the presence of active carditis there was evidence of increasing severity of the existent carditis. One of the children died six weeks after the last injection of vaccine. In the other two patients eventual improvement occurred. The carditis might have taken a similarly unfavorable course under conservative treatment. In a disease with such great variability as rheumatism, it is difficult to draw conclusions on the basis of a few cases. The authors cannot help feeling however, that the use of intravenous injections of typhoid vaccine is not harmless in the presence of rheumatic infection. On the other hand a large proportion of patients with chorea do not present carditis. It is in these children without carditis that the use of typhoid vaccine seems justifiable. Perhaps it may prove to be a valuable procedure even in certain nonchoreic forms of nervousness in children. The sedimentation test is the best single laboratory guide to the presence of rheumatic infection but it is not infallible. In the presence of an increased sedimentation rate, conservative measures in the treatment of chorea seem indicated. An early depression and subsequent rise of the number of granulocytes occur during the febrile reaction following intravenous vaccination. Persistent leukopenia in one of the authors' patients was considered an indication for cessation of the administration of vaccine. It may be advisable to control this method of therapy by frequent determinations of the white blood cell count. Otherwise repeated daily use of an agent that depresses the formation of granulocytes may produce harm either through an increase in the rheumatic disease itself or through the development of agranulocytic angina.

Use of Convalescent Blood in Whooping Cough—Bradford gave fifty-eight children, chiefly less than 3 years of age, injections either of 10 cc. of serum taken in the eighth week of convalescence or from 10 to 20 cc of whole blood taken from an adult (parent) who had had the disease previously.

Forty-four of the children were obliged to remain in homes in which one or more cases existed. Twenty-seven of this group received the injections during the incubation period. The disease developed in fifteen but was mild in ten. There was one complication. Of twenty children used as controls, eight had a mild form of the disease, eight, average, and four, severe. Complications developed in four. In seventeen children exposed in the family who received the preventive vaccine after symptoms of coryza existed there was no indication that the course of the disease was modified. In a group of sixteen patients exposed outside the family, nine were given injections during the incubation period, and the number completely protected was so great as to suggest that the exposures may not have been genuine. From evidence obtained by observation of treated patients exposed in the home along with suitable controls and from the survey of the literature to date, it seems probable that immune blood is effective in the prevention and modification of whooping cough if given before the catarrhal symptoms appear. If given after the disease is established, favorable results are less apparent.

Congenital Lymphangiectasis—Mason and Allen present five cases of congenital lymphedema that have been observed at the Mayo Clinic. The macroscopic and microscopic observations of tissues that were removed during the Kondoleon type of operation were characterized by the replacement of normal subcutaneous fat with fibrous tissue and with enlarged lymphatic vessels, chiefly in the region of the deep fascia. The authors feel that the microscopic appearance of the tissue is so characteristic that the term congenital lymphangiectasis should be used to replace the term congenital lymphedema, because congenital lymphangiectasis describes the condition better.

Ascaris Sensitivity in Man.—Jones and Kingscote found that twenty-seven of 108 subjects, mostly veterinary undergraduates selected at random, gave positive reactions to a scratch test with 5 per cent saline extract of pig ascaris. A period of exposure seems to be a necessary precursor and continued reexposure

may lead to at least partial desensitization. Various fractions of ascaris were similarly tested. In some subjects an eosinophilia followed the reaction. A positive reaction is no indication of previous infection, although previous exposure by contact may be necessary. However, continued exposure does not necessarily cause sensitization.

Fractures of the Pelvis—Conway states that in a review of fifty-six cases of pelvic fracture, admitted over a period of nineteen months, there were only four cases of accompanying genito-urinary injury. In twenty-four cases there were abdominal signs of pain, tenderness and increased muscle spasm due to retroperitoneal hemorrhage. Abdominal puncture as an adjuvant to the diagnosis of intra-abdominal injury has proved of inestimable value in positive cases. The mortality, thirteen deaths, was definitely influenced by the degree of severity of the accompanying injuries. Nine patients died within twenty-four hours following admission. Russell traction has a definite part in the reduction of sacro-iliac dislocations and distortions. In cases of suspected involvement of the bladder, direct instillation of a radiopaque substance by the urethral route with a subsequent roentgenogram is of more value than the attempt to siphon back a measured amount of instilled fluid. The mechanism of urethral injuries in children is believed to be due to a temporary diastasis of the urogenital diaphragm with concomitant tearing of the urethra, only rarely does a bony fragment lacerate the urethra. The relative infrequency of visceral complications was a principal feature of the present group of cases.

Technic for Inversion of the Intestine—Bettman points out that in the inversion of the ends of the cut intestine during an intestinal resection with side-to-side anastomosis or the inversion of the duodenal stump during the operation of partial gastrectomy the first half of the closure of the open end of the cut intestine or duodenal stump is performed as usual and the suture is left long and untied. A second suture threaded on a small full curved needle is then placed in what will be the end of the suture line, including all layers, and is tied. The curved needle is then inserted through the intestine or stump of the duodenum, piercing the mucosa about half an inch below the cut edge and emerging through the serosa (that is, from within out). If this suture is now pulled taut, the part of the cut surface of the intestine that otherwise is difficult to invert will invert easily and, if it is held taut, the closure can be completed quickly. The inversion suture is cut off flush with the intestine and will retract inside.

Symptoms of Pelvic Endometriosis—Mussey and Butsch studied the histories of fifty cases of endometriosis demonstrating that dysmenorrhea of the acquired type, which affects a woman more than 30 years of age, is suggestive of endometriosis. Pain that occurs in relation to previously normal menstrual periods whether before, during or after the period, is significant of endometriosis, although in the presence of this condition pain may occur at other times. The pain may be intermittent

at first, but it tends to assume a more constant character and to become progressively worse with successive menstrual periods, it may be increased by physical activity. Pain on defecation or rectal straining, related to the menstrual period, and diarrhea or rectal bleeding that occurs only at the menstrual period, are of distinct significance. Attacks of nausea and vomiting related to the menstrual period and accompanied by localized pain may indicate the presence of endometriosis. The clinical diagnosis of pelvic endometriosis rests largely on the history and physical observations. The latter may be definitely diagnostic, as when the growth is found in the rectovaginal septum, but the diagnosis is often elusive and it is evident that a carefully developed clinical history is of distinct value in the recognition of this condition.

- Dangers to Southerners in Northward Migration. C. A. Mills. Cincinnati.—p. 591

Intravenous Toxicity of Atabrine.—Owing to the very slow excretion or destruction of atabrine in the body, Dawson and his associates state that it seems unnecessary to employ a dose larger than 0.1 Gm. for intravenous injection for an adult. The margin of safety is probably not great, and intravenous injection should be resorted to only in emergency. The injections should be made slowly and should be timed to take several minutes for completion. The total amount of the drug injected over a period of twenty-four hours should not exceed 0.3 Gm. Untoward effects of atabrine appear to include gasping or accelerated respiration, circulatory failure, collapse, vomiting, possibly rise of temperature, psychoses, loss of appetite and of weight, abdominal pain, headache, diarrhea, yellowed sclera and rather persistent yellowing of the skin. In view of the very slow excretion or destruction of the drug in the body, it is reasonable to consider that a course of treatment with it should not be repeated within a period of approximately eight weeks, and the drug should be taken only under supervision of a physician.

Sprue. Roentgenologic Changes in Small Intestine.—Mackie and his co-workers demonstrated characteristic changes roentgenographically in the small intestine in seventeen cases of sprue. There is a striking variation in the contour and in the size of the intestinal lumen. The motor activity is markedly abnormal and frequently produces a segmental distribution of the barium sulfate. These changes may be localized or may extend throughout the entire length of the small intestine. In the duodenum the mucosal folds appear thickened and the lumen is dilated irregularly. The valvulae conniventes of the jejunum are thickened more widely separated than normal and irregular in size producing a distorted mucosal pattern. Here again the lumen frequently appears dilated a change that may be extensive or may be confined to isolated segments. The barium usually passes through the jejunum very slowly and moves irregularly. It is apt to collect in short segments of intestine that are dilated and abnormally smooth while the regions immediately adjacent are empty. The filled areas show no evidence of peristalsis. Roentgenograms taken subsequently show a similar irregular arrangement of the barium-filled intestinal segments at a lower level. At times all the barium that has left the stomach is collected in a localized pocket, while the remainder of the jejunum

and the duodenum are empty. The discharge from the stomach to the duodenum is spasmodic, corresponding apparently to the local delay in the forward progress of the opaque meal through the small intestine. The changes in the ileum are similar to those in the proximal parts of the intestine. Although the rate of passage of the barium through the small intestine is subject to wide variation, the forward progress of the opaque meal is not more rapid than normal. The specificity and response to therapy of the changes in outline of the small intestine in sprue may be significant in clarifying the mechanism of the disease. Similar changes have been observed in other conditions exhibiting clinical evidence of multiple deficiency states. The intensity and extent of the abnormalities in the small intestine vary directly with the severity of the clinical picture in sprue, and they regress under specific therapy. They may play a part in the defective absorption or utilization of essential food factors.

Treatment of Chronic Rheumatoid Arthritis.—Having demonstrated the strain of streptococcus among the many used to which a patient was most skin sensitive, Wainwright used this information as a guide to vaccine treatment. Twenty-eight patients with chronic rheumatoid arthritis received streptococcus vaccine intravenously at weekly intervals for periods varying from two months to more than one year, and since then seventeen additional patients have been treated. All foci of infection were removed. The vaccines used were prepared from hemolytic strains in all but two instances. The patients received weekly intravenous injections of vaccine prepared from the strain to which they had shown the maximal skin sensitivity. The initial dose was approximately 5 million organisms contained in 0.5 cc. of vaccine. The dose was increased by 0.5 cc., provided no constitutional reaction occurred. Febrile reactions were avoided by beginning with a small dose and increasing the dose sufficiently slowly. The increase in dosage was gaged by the patient's response and no set schedule of dosage was followed. Although no constitutional reactions occurred, as a rule the patients complained of focal reactions for about twenty-four hours after each injection. This reaction was manifested by increased pain in the involved joints, but after the reaction subsided the symptoms were usually improved. The improvement came about slowly, making its appearance in from four to six weeks after treatment was begun. Joints have flared up during treatment, but would often subside in a shorter time than was the patient's previous experience. In some cases definite improvement has been observed up to a point at which the arthritis seemed to become stationary, and beyond this point no further improvement was obtained. The benefit derived manifested itself by decreased pain, reduced swelling of the joints and of the surrounding soft tissues, and increased mobility of the joints. Streptococcus vaccine was given intravenously to two patients suffering from active pulmonary tuberculosis. The increase in dosage was made cautiously, and constitutional reactions were avoided. In both cases the arthritis has improved during treatment. Not only has the pulmonary tuberculosis not progressed but healing has gone on, and in one

case the pulmonary lesion is now considered inactive. During treatment the skin reaction to the strain used has regularly diminished in intensity and in most instances has entirely disappeared. Agglutinins have appeared in the patient's serums for the strain employed, when not already present, and when present, as was the case with the hemolytic strains, the titer has materially increased during treatment. In all cases treated the sedimentation rate has been elevated, in some much higher than in others. The highest rate at the beginning of treatment was 54 mm in one hour and the lowest was 15 mm. Fifteen of the forty-five cases treated either have not improved or else the change that has come about has been so slight that improvement was questionable. In none of the cases has the arthritis been made worse by treatment and no untoward reactions have occurred.

Internal Myxedema—Escamilla and his associates cite a case of hypothyroidism that showed ascites, cardiac, intestinal and bladder atony, secondary anemia, menorrhagia and associated carotenemia. The ascitic fluid was thought to be due to the hypothyroidism and showed a protein content above the average, but not as high as in some cases that have been reported previously. The cardiac observations were typical of myxedematous heart without decompensation. Atony of the bladder is thought to be more common than previously reported. The patient was followed over a period of thirteen months and all symptoms and signs showed improvement on thyroid therapy except the anemia, for the improvement of which iron was necessary in addition to the thyroid. An exploratory laparotomy performed for symptoms simulating partial intestinal obstruction showed no evidence of other etiology for the ascites. The authors suggest that the term "internal myxedema" would best describe the manifestations observed in their patient.

Hemorrhage in Cancer of Lung—Lederer believes that the emphasis on hemoptysis as a symptom of lung cancer, together with the presentation of case reports from the literature of fatal hemorrhage, serves to illustrate the possibilities of bronchoscopic interference in these cases. His experience, coupled with the proliferative and ulcerative changes found on postmortem examination in these pulmonary lesions, causes him to believe that similar fatalities have occurred before without special attention being directed to this possibility. The mechanical effort of a bronchoscopic observation, performed under the best conditions, may be sufficient strain to provoke a hemorrhage from a vessel whose walls are near a malignant mass and perhaps even invaded by the neoplasm. There can be no question as to the advisability of the bronchoscopic procedure, but it is well to bear in mind the possibility of hemorrhage.

Tertiary Syphilitic Lesions of Nasal Mucosa—Lupton states that syphilitic infiltration of the nasal mucosa is a definite clinical entity and should be considered in the differential diagnosis of every doubtful lesion of the nasal mucosa. Because of the preponderance of vascular and lymphatic elements present in the mucosa of the direct airways of the nose, specific infiltrative lesions are more frequently found here than in the mucosa lining the accessory sinuses. Biopsy of the nasal mucosa is of extreme value to the clinician in questionable cases. Should the section show at least presumptive and supportive evidence of a chronic syphilitic rhinitis, it will have served its purpose well by suggesting a specific background. Negative blood examinations should not preclude the possibility of a specific infection in questionable lesions of the nasal mucosa, and in doubtful cases one should resort to careful study of the spinal fluid.

Diagnostic Value of Phosphatase in Bone Tumors—Simmons and Franseen made observations on seventy two cases of bone tumors of various types. They found that the plasma phosphatase reading is normal or low in nonmalignant bone tumors, normal or slightly elevated in multiple myeloma and in endothelial myeloma (Ewing sarcoma), normal or slightly elevated in the giant cell tumor of bone, considerably elevated in malignant disease metastatic in bone, and this fact may be of value in differentiating the multiple bone metastases of carcinoma from endothelial myeloma and multiple myeloma, and consistently high in osteogenic sarcoma of the osteoblastic type. In the osteolytic type (one case) it is approximately the same as in the group of metastatic carcinoma and giant cell tumor. Following surgical removal of an osteogenic sarcoma, the plasma phosphatase falls to normal in the course of from two to three weeks but again becomes elevated when there are demonstrable metastases. The recurrent tumor must attain an appreciable size before an increased plasma phosphatase activity can be demonstrated. In individuals dying of osteogenic sarcoma the activity diminishes shortly before death. Radiation treatment of an osteogenic sarcoma caused a temporary diminution in the

plasma phosphatase activity in one case. The plasma phosphatase activity bears a definite relation to that of the tumor tissue. The high phosphatase activity of the tumor tissue in osteogenic sarcoma is an example of a neoplastic cell continuing to produce the physiologic secretion of the normal cell from which it is derived. In one case of myositis ossificans the plasma reading was high at the time of osteoblastic activity in the lesion.

Circulatory Disturbances Caused by Intestinal Obstruction.—Gatch and Culbertson devised experiments to disclose the relation between intra-intestinal pressure and blood flow through the intestinal wall and to demonstrate the effect of various amounts of intra-intestinal pressure on its viability, motility, secretory activity and power of absorption. Their experiments demonstrated that: 1 Toxic material present in the lumen or wall of the obstructed intestine may reach the systemic circulation by way of the mesenteric vessels and by way of the peritoneal cavity. 2 Before the passage of any toxins by either route or under any conditions can occur, injury to the mucosa must exist. 3 Injury observed under clinical conditions to the mucosa of the obstructed intestine is due practically to distention and venous congestion. 4 Any passage of toxins from an intestine with devitalized mucosa must be transperitoneal as long as its circulation is stopped by pressure or obstruction, by way of the mesentery if its circulation is present. Distention causes a decrease in the blood flow through the intestinal wall, which is in direct proportion to the elevation of the pressure. It almost stops the blood flow when it reaches the level of the diastolic blood pressure. At this level it stops all absorption by way of the mesentery. Transperitoneal absorption then occurs. Distention sufficient to arrest the circulation of the intestine will devitalize the intestinal mucosa in from five to fifteen hours. This devitalization is demonstrated by the loss of selective absorption by the mucosa. It then permits the passage of toxic substances present in the normal and obstructed intestine. The absorption of materials that are normally absorbed by the intestine, except water and probably inert gases, proceeds at a relatively uniform rate in the presence of intra-intestinal pressures between zero and the diastolic blood pressure. Venous obstruction subjects the capillaries of the intestine to the full force of the systolic blood pressure. The circulation of the obstructed intestine is not greatly influenced by the increased intra-abdominal pressure that accompanies intestinal obstruction. The blood flow through distended loops must be lessened by any weakness of the systemic circulation. In the clinical management of patients suffering from advanced obstruction it seems desirable to deflate the intestine gradually before the operative relief of the obstruction is undertaken, otherwise the barriers against absorption of toxins by way of the peritoneum, and against their rapid absorption by way of the mesentery, may be broken down.

Splenectomy in Childhood.—As a large proportion of the cases of fetal erythroblastosis terminate fatally within a short time and as the character of the hemolysis seemed to Penberthy and Cooley strongly suggestive of perverted splenic activity, they performed splenectomy in two cases. Splenectomy promptly checked the rapidly progressing hemolytic anemia. Because of the gravity of the condition, they believe that the operation should be performed as soon as the diagnosis is made. Results are reported of splenectomies performed on children: in six for hemolytic icterus, in four for sickle cell anemia, in five for erythroblastic anemia in six for hemorrhagic purpura, and in five for different types of splenic anemia. The patients with hemolytic icterus seem to have recovered completely from the primary disorder, with no signs of recurrence. One has had trouble from postoperative adhesions and duodenal ulcer. In the cases of sickle cell anemia the condition has been little benefited by the operation but the abdominal and joint crises have been alleviated, and in one case epileptiform attacks ceased after the splenectomy. Splenectomy in erythroblastic anemia has not appreciably altered the course of the anemia. It is followed by a remarkable permanent increase in circulating normoblasts. The patients are considerably relieved by freedom from the weight of the greatly enlarged spleen and may live somewhat longer. Results in hemorrhagic purpura are nearly as good as in hemolytic icterus. Four patients recovered com-

pletely, one has had a single slight recurrence, and one, operated on during a very severe bleeding episode, died. Here, as in hemolytic icterus the authors do not operate during crises, except as a last resort. Two patients exhibiting the syndrome with splenomegaly, leukopenia and anemia, often called the first state of Banti's disease, seem to have been cured by splenectomy. Of three having splenomegaly and anemia without the characteristic leukopenia, apparently secondary to infection, one has died and two have gone on to the late stages of the Banti syndrome with hemorrhage and cirrhosis.

Colectomy for Adenomatosis and Pseudopolyposis.—Rankin gives an additional report of a series of five cases of colectomy for diffuse adenomatosis and complicated chronic ulcerative colitis. Six cases were reported previously in which the entire colon and rectum were removed by multiple procedures. In four of the present cases the colon was removed down to the rectosigmoid juncture, in the other, total colectomy was done. In two cases of the chronic ulcerative colitis variety it is probable that the rectum will have to be removed subsequently, although the patients show marked improvement. In one case the reestablishment of the continuity of the gastrointestinal tract was carried out at the third stage following destruction of the rectal polyps by fulguration. There was one operative death following the second stage colectomy and in this case fulguration had been carried out on the rectal polyps and the plan was to transplant it subsequently at a third maneuver into the terminal ileum. The disappearance of diffuse rectal polyps following vigorous fulguration is surprising and encourages the belief that this plan, which has heretofore been considered an alternative one and available only when the rectal polyps were few, may be available to a great many more of these cases. Technical steps of importance are the preservation of the omentum in the chronic ulcerative colitis group and in the case of adenomatosis when there is no suggestion of a malignant condition. A second technical point of advantage is the method of handling the rectal stump, which turns in with difficulty in many of the polyposis cases and not at all in the chronic ulcerative colitis variety. The stump must be closed over as accurately as possible, covered with whatever tissues there are and if there is any question of leakage, wrapped in iodoform gauze and a rubber tissue to establish a drainage track in the event that the suture line fails to hold. Of the eleven patients, one died eighteen months following the complete operation from recurrence of carcinoma which had developed on the polyps and which was diagnosed at exploration. A second patient died two years later following a hysterectomy performed elsewhere. One patient died in the hospital following the second stage operation, and the remaining eight patients are alive and well and have all returned to their various occupations.

Otologic Changes in Oculogyric Crises.—Shapiro examined six patients, four men and two women, aged from 21 to 39 years, suffering from cephalo-oculogyric crises. Four had tremors, rigidity and other evidence of parkinsonism, two presented no striking neurologic symptoms but were considered

by neurologists to have a probable postencephalitic state. Weakness of the muscles of convergence and accommodation or jerky voluntary movements of the eyes were present in five. Cochlear function was good in all. With the exception of one instance, no spontaneous vestibular abnormality was present. Vestibular stimulation revealed absence of, or diminished, susceptibility in all the patients, perverted or absent vertigo in two, perverted past pointing in one, absence of falling in one, who also showed perverted vertigo, and absence or impairment of nystagmus downward as induced by rotation with the head over the shoulder in two. Optic nystagmus in all cardinal directions could be induced in the intervals between attacks in all the patients. Five attacks were witnessed, there was upward or oblique deviation of the head and eyes in four and horizontal deviation in one. The ability to induce vestibular nystagmus while the patient was in a crisis was apparently proportional to the strength of the stimulus applied and the severity of the spasm. The facts available, including the postmortem studies, point definitely to the midbrain as the seat of the pathologic changes. None of the usual changes in the basal ganglia and tracts of this region that are commonly found in chronic parkinsonism can be held responsible, as these have been demonstrated many times in patients who during life had no ocular deviations. The views of Muskens, who regarded oculogyric crises as forced movements due to the interruption of pathways connecting the end stations of the secondary vestibular neurons to the pallidum, offer an explanation which, while based on experimental evidence, does not run counter to the clinical and anatomic data available. There are certain differences between the forced movements elicited by Muskens and other authors in animals and spasmodic deviations of the head and eyes in patients in the postencephalitic state. These can be readily understood in the light of the changing role of the vestibular apparatus in man as contrasted with that in animals and do not, by themselves, constitute an argument against the conclusions of Muskens.

Relationship of Sinusitis Allergy and the Common Cold.—The common cold, in Sewall's opinion, is always due to the pus-forming bacteria, and they are always activated by a filtrable virus. There must therefore be a never ending source of this virus. He believes that chronic sinusitis is the chief source, the endemic reservoir, for the perpetuation of the common cold. He does not mean that one must have chronic sinusitis to contract a cold but that chronic sinusitis must exist in some one for the pus germs lying in the chronically diseased mucosa to produce the virus capable of activating the same bacteria in others. The common pus-forming germs are the direct cause. They lie in the mucosa of the chronically diseased sinus. The lapse of immunity, associated with the factors that reduce resistance, allows them to become active. This activity is associated with the production of a virus that not only promotes the virulence of the sinus infection but, discharged as a secretion from the sinus, activates the same type of bacteria lying in a saprophytic state on the mucous membranes of that person. The result is the common cold engrafted on a chronic sinusitis. The virus secreted as nasal discharge will activate the same type of pus germs lying in a saprophytic state in the nose and throat of another person and cause an acute cold. Thus the vicious circle of the common cold appears

never ending until such time as the endemic reservoir in the chronic sinus may be rendered innocuous or removed. The morbid changes that characterize a common cold depend on the histologic structure of the mucosa. One can distinguish three types of mucous membrane, the normal adult mucosa, the altered mucosa and the diseased mucosa. Each is subject to infection and determines the character of the inflammatory process.

Cellular Reaction to Silica—Fallon and Banting studied the cellular reaction produced in rabbits by the subcutaneous injection of hand picked quartz that had been reduced to a fine powder. Weighed quantities of the material were added to distilled water so that each cubic centimeter contained 40 or 60 mg of the powder. The suspension was autoclaved for thirty minutes and 0.5 cc. was injected subcutaneously under aseptic conditions into the external surface of the ears of twenty-four rabbits. For microscopic examination of the effects, sections of the ear were punched out with a large cork borer. The sections taken at ten minute intervals during the first sixty minutes showed a gradually decreasing amount of intercellular fluid. In the sections taken between thirty minutes and six days after the injection of quartz particles the reaction was typical of acute inflammation. The quartz particles appear to have a toxic effect on the polymorphonuclear and mononuclear leukocytes and small lymphocytes that enter the aggregations. All these cells are rapidly broken up in this location. Similar cells retain their normal characteristics when they remain in the surrounding areolar tissue. In as short a time as six days the quartz particles become so intimately mixed with cell debris that the aggregations have an appearance of organization. In the sections taken six days after the injection of quartz suspensions the microscopic picture is that of subacute inflammation. The areolar tissue on one side of the cartilage is extensively

infiltrated by polymorphonuclear and mononuclear leukocytes and fewer lymphocytes. The mononuclear leukocytes are seen in great numbers in the aggregations of silica particles, where they soon become disintegrated, leaving a framework of poorly staining cells and cellular debris throughout the masses of particles. It is along this framework that the histiocytes later advance into the central portions of the aggregations. Beginning as early as the sixth day and increasing as time goes on, the histopathologic picture gradually changes to that of chronic inflammation. The tissue histiocytes and adventitial cells of the blood vessels are mobilized, take on an ameboid appearance and advance toward the aggregations of quartz particles and cellular debris. Many of these cells are seen in mitotic division. Active phagocytosis of the cellular debris and engulfing of the quartz particles are carried on by the histiocytes until the entire mass, except for a few of the larger quartz particles, is taken up by the histiocytes. This process is complete in the smaller aggregations by the third, and, in the larger, by the sixth week. While changes are taking place in the aggregations there is an active granulation tissue formation in the surrounding areolar tissue. Numerous thin walled blood vessels are formed and carried into the nodules in long, thin strands of elongated, spindle-shaped cells. From the sixth week onward the microscopic picture is that of scar tissue formation. The phagocytic cells become elongated and spindle shaped. This process begins at the periphery and extends toward the central portions of the nodules. Hyalinization begins at the outer margin and follows to the center of the nodule. As this change progresses there is a proportionate decrease in cellularity. The cells disappear by a gradual diminution in size, and simultaneously there develops intercellularly a firm fibrous tissue, which ultimately forms the silicotic nodules. The cells in the central portions of some of the nodules break down and disappear, leaving irregularly rounded collections of a very finely granular substance. This has the appearance of caseous necrotic material and by micro-incineration is shown to contain a large amount of siliceous material.

Diagnosis and Symptoms of Carcinoma of Colon—

Shaw says that the symptoms and signs of carcinoma of the right half of the large intestine are not diagnostic but suggestive. They are pain usually a dull inconstant pain, fairly well localized to the right side, indigestion of a vague type, anemia and weakness, the anemia being marked, with a red count often

near three million, a decreased hemoglobin and a picture suggestive of pernicious anemia, change of intestinal habit of the patient, whether constipation, diarrhea or alternation of the two, occult blood in the stool, which is a fairly constant finding, but melena is usually a late symptom in lesions of the right colon, a tumor mass in the right abdomen, usually movable and somewhat tender, which is often found and is the presenting symptom, loss of weight and cachexia as late manifestations, usually meaning a far advanced case, and roentgen observations. Signs and symptoms of carcinoma of the left half of the colon are obstruction, either complete or partial, change in the intestinal habit, again the most constant symptom, being usually a progressive constipation, blood and mucus in the stools of practically all these patients, rumbling, visible peristalsis, the feeling and hearing of gas and liquid feces as they pass through the constricted portion of the colon, which is frequently noted and the patient may even be able to localize the lesion by these symptoms, a tumor mass, not often found owing partially to the smaller size of most of these tumors and also to the fact that the sigmoid is deeply situated and not easily palpated (rectal examination will reveal many of these tumors), and roentgen observations. In the differential diagnosis the most common conditions that cause confusion are chronic ulcerative colitis, tuberculous colitis, diverticulitis, appendical abscess and functional diseases of the colon. These are probably best treated for a short time as functional cases, after which a careful reexamination should be made for persistence of the defects.

Rocky Mountain Spotted Fever Vaccine—Parker states that the data from ten years use of the Public Health Service vaccine for the prevention of Rocky Mountain spotted fever justify a broadening of the scope of previously published conclusions with regard to its prophylactic usefulness. The vaccine has definite value. The degree and duration of protection vary with the vaccinated person and with the degree of virulence of an infecting strain of spotted fever virus. The average person vaccinated in the spring retains a considerable degree of immunity during at least the remainder of that year. This degree of immunity is usually sufficient to afford full protection against the relatively mild strains of spotted fever but apparently is progressively less effective as the virus virulence is increased. The degree of protection against the highly fatal type is sufficient to ameliorate markedly the usual very severe course of infection and to ensure the recovery of most persons, the complete protection of occasional persons is not unlikely. Children

are perhaps better protected than adults, and among them full protection against virus strains of high virulence may be more frequent. If a person is infected during the vaccination period, there is a strong probability that the subsequent clinical course of the disease will be affected favorably, even in areas of high case fatality rate. In areas in which relatively mild infections prevail and the incubation period is prolonged, the administration of vaccine as soon as possible after tick bite may ameliorate an impending infection. This appears particularly probable in persons who have been vaccinated in previous years. This procedure is not recommended in areas of highly fatal infections in which the incubation period is short, unless the person has been previously vaccinated. It is probable that a considerable percentage of vaccinated persons carry an uncertain degree of immunity over into the second year, even against highly virulent virus. The degree of this residual immunity appears to be greater in persons who have been vaccinated two or more successive years. The evidence as to whether or not any degree of immunity is carried beyond the second year is less suggestive. Until more definite data are available, however, it is necessary that the vaccination of exposed persons be repeated each year and that three injections of 2 cc, instead of the usual two, be used in areas of high virulence, especially the first year that vaccine is given. Of persons vaccinated and infected the same year, those who have received vaccine two or more successive years appear to have greater resistance than those who have received vaccine only one year.

Production of Enterotoxigenic Substance by Bacteria—Jordan and Burrows found that freshly isolated bacteria of various kinds (staphylococci, streptococci, *Proteus*, *Bacterium coli*, *Bacterium aerogenes*, *Salmonella aertrycke*) when grown under suitable conditions are capable of producing a substance that causes vomiting and other gastro-intestinal symptoms in monkeys. The use of a custard medium or the addition of starch to ordinary medium favors the production of the enterotoxigenic substance. By successive transfers on starch medium the property of producing enterotoxigenic substance was restored to a number of bacterial strains that were originally positive but that had long given negative results. Although the procedures described do not invariably result in the production of toxic filtrates, it has always been possible to restore this property eventually to a given strain by intensive and repeated attempts. Certain bacteria that had never yielded enterotoxigenic filtrates in previous laboratory tests gave positive results after they had been transferred on starch medium.

Treatment of Perforated Duodenal Ulcer—Brinkley employed simple closure of the perforation and jejunostomy with drainage of the culdesac in his last five cases of acute perforated duodenal ulcer, in which operation was performed during the last seventeen months. There was one death. The postoperative treatment consists in elevating the head of the bed 12 inches. 500 cc of a 5 per cent solution of dextrose is immediately given intravenously and by the flush method as proctoclysis, and gastric lavage with a warm solution of sodium bicarbonate is given with the duodenal tube from every four to six hours for the first twenty-four hours and continued if necessary. Every four hours 1 cc of digifoline or digitalone is given hypodermically, and one-third grain (0.022 Gm) of a mixture of opium and alkaloids every four to six hours if required. Fluids are withheld by mouth. Feedings every two hours are started through the jejunostomy tube at once. For the first two or three days 2 ounces (60 Gm) of predigested beef in 2 ounces (60 cc.) of warm water is given at one feeding, and 4 ounces (120 cc) of peptonized milk at the next feeding. After this period a more liberal diet is allowed. Water is given between feedings. The drainage tube is removed on the third to the fifth day. Water is allowed by mouth in small quantities on the fifth day, liquids on the eighth to the tenth day. The catheter and sutures are removed on the tenth to the twelfth day and an ulcer diet is started on the fourteenth day. The patient is usually allowed to sit up in bed at the beginning of the third week and is discharged from the hospital during the third or fourth week.

Lymphosarcoma of Stomach—The symptomatology of the case that Hameed presents did not indicate a new growth of the stomach, as it consisted only of intense anemia, optic neuritis and some wasting of the muscles of the extremities. Whether the neuritis was due to a toxic condition or to an actual infiltration in the spinal cord and its nerves could not be ascertained as permission to remove the spinal cord was withheld. There was leukopenia and some relative increase in lymphocytes. The former condition can be accounted for by aplasia of the bone marrow. Finally, pseudoleukemia of the gastro-intestinal tract is rarely an acute condition and shows no infiltration in organs other than the lymph nodes, while the onset of the condition was somewhat acute and showed infiltration in other organs as well, including the pancreas. Hodgkin's disease was excluded on account of the absence of increased reticular fibers and of large mononuclear and giant cells. Moreover, in Hodgkin's disease enlargement of lymph glands is a common feature, which was not present in the author's case. The hyperchromicity, mitotic division of the cells and extreme degree of cellular infiltration, both in the stomach and in other organs, made the diagnosis of lymphosarcoma quite clear. Metastatic deposits in the liver, the Peyer's patches of the small intestine, the pancreas, kidneys, spleen and medullary cavities of the long bones were interesting features. The fact that the mesenteric and the lymph glands along the greater and smaller curvatures of the stomach were not appreciably enlarged pointed toward the spread of the disease through the blood vessels and not through the lymphatics. The stomach, being the primary organ affected, was infiltrated from the cardia to the pylorus and gave rise to polypoid growths at places.

Dietetic Factor Determining Dextrose Tolerance and Sensitivity to Insulin of Healthy Men.—Himsworth describes experiments on healthy human subjects concerning the effect of change in the diet on the dextrose tolerance and the sensitivity to insulin. In healthy subjects the improvement in dextrose tolerance consequent on the change from a low-carbohydrate high fat diet to a high carbohydrate low-fat diet, is not determined by change in the caloric value or ketogenic-antiketogenic ratio, or change in the fat or protein content of the diet, but solely by the amount of carbohydrate in the diet. On the basis of these experiments the author has constructed

a "determination curve of dextrose tolerance" that expresses for healthy subjects the relationship between the change in sugar tolerance and the change in the amount of dietary carbohydrate. The efficiency with which a standard dose of crystalline insulin acts on the blood sugar is determined by the carbohydrate content of the diet so that the greater the amount of carbohydrate in the diet the greater the sensitivity of the organism to insulin. The relationship in healthy subjects between the change in insulin sensitivity and the change in the amount of carbohydrate in the diet can be expressed as a "determination curve of insulin sensitivity." A correlation between the change in dextrose tolerance and the change in insulin sensitivity is such that it can be expressed as a straight line inclined at an angle of 45 degrees to the abscissa. The development of insulin sensitivity is independent of the dose of insulin used as the standard test dose. The quantity of pancreatic insulin brought into action in response to a standard dose of dextrose is constant in amount whatever the degree of tolerance indicated by the blood sugar curve. The change in dextrose tolerance consequent on the change in composition of the diet from a low-carbohydrate high-fat to a high-carbohydrate low-fat diet is completely accounted for by the change in sensitivity of the individual to the insulin secreted by his own pancreas. The bearing of these results on the apparently acute development of diabetes mellitus in man and on the dietetic therapeutics of this disease is discussed.

Diet Prior to Onset of Diabetes—Himsworth and Marshall compared the diet of 143 diabetic patients prior to the onset of their disease with the diet of two comparable groups (137 and 121 persons) of normal subjects. The qualitative method, which by questioning aimed at discovering whether the diet differed from the normal, and the quantitative method in which the subjects, from foodstuffs of known composition, chose a day's intake in food, which was then expressed in terms of carbohydrate, protein and fat, were the methods employed in determining the nature of the diet. Both methods reveal that the majority of diabetic patients, prior to the onset of diabetes, prefer diets containing an excessive proportion of fat, and that a smaller number of these persons than normal subjects prefer diets containing an excessive proportion of carbohydrate foods. The diabetic patients chose diets of greater caloric value and containing larger amounts of carbohydrate, protein and fat. This increased consumption arises possibly from an error inherent in the method used. The difference between the diabetic and normal subjects in the amount of fat consumed is, however, from a statistical point of view, so much greater than the difference in consumption of carbohydrate and protein that significance may be attached to it. The diet of diabetic patients before the onset of the disease, in comparison with the diet of normal subjects, contains the same proportion of protein, a diminished proportion of carbohydrate and an increased proportion of fat. Similar diets impair sugar tolerance and insulin sensitization in nondiabetic subjects, and the ingestion of such a diet by a potentially diabetic individual would favor the appearance of the disease. The habitual ingestion of a diet containing a diminished proportion of carbohydrate may cause progressive permanent impairment of sugar tolerance and insulin sensitivity, so that diabetes mellitus results in the course of time.

Diet and Incidence of Diabetes Mellitus—Himsworth presents data showing the different diets eaten by different races, nations and social classes throughout the world and makes a correlation between dietary preference and the incidence of diabetes mellitus. The incidence rate of diabetes mellitus has been assumed to be reflected by the mortality rate. The available data do not suggest that excessive consumption of sugar and overindulgence in alcohol play a part in the etiology of diabetes mellitus. The data with regard to the total quantity of food eaten show that there is no definite correlation between the rise in the incidence of diabetes and overeating. Prediabetic obesity is an effect of the type of diet eaten. A close correlation exists between the incidence of diabetes mellitus in different races, nations and social classes and the proportionate composition of the diet. A high proportion of carbohydrate and low proportion of fat is found in all cases to be associated with low diabetic incidence, while a low pro-

portion of carbohydrate and a high proportion of fat are associated with a high incidence. The available information suggests that the different diets chosen vary little in calory value. The incidence of diabetes is high when relatively low-carbohydrate diets are taken, and the incidence is low when relatively high-carbohydrate diets are chosen. In view of previous results, the ingestion of a relatively low-carbohydrate diet is the factor determining the onset of diabetes mellitus in individuals with a predisposition to the disease, and, if a high-carbohydrate diet had been taken, a considerable proportion of these persons would not have developed diabetes.

*Allergic Factor in Etiology of Nonspecific Colitis Dorothy C Hare—p 767

Allergic Factor in Etiology of Nonspecific Colitis—From a study of thirty-eight cases, Hare believes that there is a possibility that allergic factors are of importance in the etiology of nonspecific colitis. Information was sought in these cases with regard to the occurrence of the allergic disorders of asthma, hay fever, spasmodic rhinorrhea, migraine, bilious attacks, urticaria, eczema and epilepsy. Food idiosyncrasies and appetite in childhood were also the subject of inquiry. The incidence of the allergies among the general population was studied by Bruce Pearson (1933), who found that 26 per cent of healthy adults have either a personal or a familial history of allergy. It may therefore be significant that among these colitis patients as many as thirty-two of thirty-eight patients, 85 per cent, gave a personal or family history of allergy. The patients studied were all women and, with two exceptions, were treated as inpatients, the usual methods of investigation and diagnosis were employed, including sigmoidoscopy, roentgenoscopy and stool examinations. The diagnosis of this form of colitis has been based on the appearance of the mucous membrane, which is abnormally granular and congested and bleeds readily on touch. Actual ulceration may or may not be present. The term nonspecific colitis is used to include "ulcerative" and "hemorrhagic" colitis but not "mucocomembranous" colitis. Roentgen examination may show little change in the early cases and diagnostic appearances in later conditions. The stools contain blood and mucus during some part of the attack.

Clinical Value of Chest Radiogram K Dunham—p 33

Squamous Carcinoma of Lung in Asbestosis—Gloyne reports two cases of squamous carcinoma of the lung. One patient survived nine years after an exposure of eight years to asbestos dust as a spinner, the other lived for fifteen years after exposures of six months and thirteen months. In both cases the occupational history went back to the war years, the malignant lesions were very small and were not recognized during life. The carcinomas appeared to arise in the wall of a small bronchus and to grow into and extend along the lumen. Serial sections suggested that the growths were a continuous prolongation rather than a series of isolated units, though it was not possible to indicate a definite starting point. These prolongations were hollow in places, showing a degenerating layer of cells round a central empty space and an external ring of keratinized squamous cells. The growths

were in a portion of lung in which the asbestosis was fairly advanced. The advancing prolongations of the neoplasms insinuated themselves between the collagenous fibers of the pneumoconiosis. Death had occurred before the tumor had attained a size capable of affecting vital parts. Secondary deposits or even extension to mediastinal glands had not occurred. Pigment, asbestos fibers and asbestosis bodies were pushed aside by the advancing growth. The true squamous nature of the tumor was evident from the presence of prickly cells, keratinization and cell nests. The asbestosis, though fairly advanced, was not sufficiently advanced to cause death. A small meningeal hemorrhage terminated life in the first case. Compared with the squamous carcinoma of the lung in general, as it reaches the postmortem room, the growths were unusually small. The author makes the suggestion that in asbestosis a small tumor turns the scale, just as bronchitis with early bronchopneumonia will do, probably as a result of toxemia. He has observed a similar occurrence in a case of oat cell carcinoma with asbestosis.

Massive Tuberculosis of Tonsils—Hudson and Wollaston cite a case of tuberculosis of the tonsils in which, in view of the history of frequent attacks of tonsillitis during the last two years with enlargement of the glands each lasting about a fortnight, and the microscopic appearance of the tonsils, it seems possible that the tonsils were the primary lesion and that the lung became infected from them during attacks of bronchitis. From the rapidity with which the disease spread in the lung there can have been very little resistance to tuberculosis, such as would have been the case if the present infection was a reactivation of an old childhood focus in the tracheal glands. At present there are no signs of infection anywhere else, and now that the tonsils have been removed and the diseased lung is collapsed successfully the prognosis should be fairly good, though sudden activity of the miliary type of tuberculosis or a meningitis is always a possibility.

*Experimental Study on Virus of Measles T. Taniguchi M. Hosokawa S. Kuga and K. Terada—p 577

Experimental Study on Virus of Measles—Taniguchi and his co-workers isolated five strains of a kind of virus by serial intratesticular inoculations into rabbits with nasopharyngeal washings or blood from patients having measles. Three strains were examined immunologically and are proved to be identical. They are clearly distinguished from the viruses of vaccinia, varicella, herpes simplex, pemphigus and encephalitis from the immunologic standpoint. The virus is also differentiated from the virus III. A specific virulicidin against this virus is contained in the convalescent serum of measles. When susceptible persons are inoculated with this virus, typical measles supervenes. The elementary body that is assumed to be the virus of this experimental measles is demonstrated. The authors therefore conclude that the virus which they conveyed to the rabbit was most probably that of measles, and that the elementary body encountered must have been the virus of measles.

*Existence of Tuberculous Ultravirus H Plotz—p 1428

Survival of Dog Having Complete Pancreatic Fistula J Bottin—p 1430

Tuberculous Ultravirus—Plotz calls attention to the fact that the term ultravirus is a misnomer when coupled with "tuberculous," since its properties are not comparable to those of the true ultravirus. For example, a lasting immunity usually succeeds infection with the latter, they are filtrable, invisible, and can be cultivated only in the presence of living cells. The "tuberculous ultravirus," however, is active only in high doses and it does not regularly produce disease, specific lesions or immunity. The filtrates are not always active and cannot be cultivated in the presence of living cells. There are, moreover, numerous evidences that the tubercle bacillus can pass through the filters. It thus becomes unnecessary to postulate a filtrable form and, in the author's opinion, no convincing experimental proof of this form has yet been advanced.

*Why Is Tuberculous Infection Allergizing and not Vaccinating? R Pons—p 1477

Allergy and Immunity in Tuberculosis—Pons discusses the factors determining the primarily allergic nature of tuberculosis. The virulent diseases which liberate most protein are the more immunizing, those liberating less protein are the more sensitizing or allergizing. The latter condition is largely fulfilled by tuberculous infection. The proteins of Koch's bacillus are without invasive powers in the well organism, and experience has shown that they are good anaphylactic and poor immunizing reactors. More than any other disease, tuberculous infection provides the conditions necessary for good sensitization: discrete infection, local growth of the organism which does not favor resorption of the microbial proteins, organism poor in proteins, and, contrary to most other infections, long in vivo life of the bacillus.

*Behavior of Epinephrine in Blood After Operation Determination by Viale's Reaction M Teppati—p 709

Conservative Operation for Controlling Postoperative Renal Hemorrhage A Slaviero—p 727

Carcinoid of Stomach—Pettinari's is the sixth case of gastric carcinoid reported in the literature and the first in which operation was performed and histologic study of the tumor made. The tumor was at the pyloric region, giving a picture of pyloric obstruction. The patient, aged 47, was discharged in a satisfactory condition two weeks after a gastroduodenal resection. The tumor proved to be seated either in the thickness of the gastric wall or under the mucous membrane, which was not involved in the process. It was made up of polymorphic epithelial cells and of some argentophil cells similar to those that exist in intestinal carcinoid. Gastric carcinoid is small, is of slow evolution and does not produce general disturbances except of a mechanical nature due to its localization as happened in the author's case. The histogenic theory that attributes the origin of intestinal carcinoid to a proliferation of embryonic remains of aberrant epithelium seems plausible in explaining the origin of gastric carcinoid in which aberrant epithelial cells probably existed in the thickness of the gastric walls.

Behavior of Epinephrine in Blood After Operation.—Teppati studied the behavior of Viale's reaction for the determination of epinephrine in the blood, in forty-four patients after several operations. The withdrawal of blood for the determi-

nation was made before the operation, shortly after it and then six, twelve and twenty-four hours later. The following changes were observed: increase of epinephrine in the blood of patients in whom the operation was performed with ether anesthesia, and transient decrease, followed by increase, in the blood of those in whom the operation was performed with spinal anesthesia (hydrochloride of benzoyldimethylaminomethylpropanol—procaine hydrochloride). It did not change in patients who were given local anesthesia. All but one of the patients in the group recovered. The patient who died had a gastroentero-anastomosis performed with ether anesthesia and had hypo-epinephrinemia for the four days during which she survived the operation.

Chromatic Reaction for Hexoses—Sánchez discovered a new colorimetric microreaction that is specific for the hexoses and their polymeric compounds, especially dextrose. It consists in producing a pink color in a mixture made up by adding 5 cc of a 1:5,000 hexose solution to 15 cc of concentrated sulfuric acid. The color appears during the reaction, becomes intensified a few minutes later and persists for several days. The determination of dextrose in the blood is done by comparing the color of the blood serum contained in the "problem tube" with that of the solution of dextrose contained in each of five tubes, numbered from 1 to 5, which form the colorimetric scale. The problem tube and those of the colorimetric scale are of the same caliber. Each of the latter contains a mixture made up of 5 cc of a homogenized solution in 15 cc of concentrated sulfuric acid, placed in the water bath at 100 C for five minutes and then cooled. However, while the solution in the "problem tube" contains 0.5 cc of the blood serum (previously deprived of its albumin and diluted in the proportion of 0.5 cc of serum to 4.5 cc of distilled water), that in the tubes of the scale contains 0.1, 0.2, 0.3, 0.4 and 0.5 cc, respectively, of a 1:1,000 solution of dextrose and 1 cc of blood serum (previously deprived of its dextrose by heating the whole blood from which it was taken at 37 C for twenty-four hours, and then of its albumin). The colors in the tubes of the scale, from 1 to 5, represent 0.2, 0.4, 0.6, 0.8 and 1 Gm of dextrose per thousand cubic centimeters of blood. The author performed the reaction on blood serum taken from whole blood heated at 37 C for twenty-four hours, and from blood deprived of fibrin and globules and then heated. He found that while whole blood loses its dextrose in less than twenty-four hours by glycolysis, the blood serum that was heated by itself, without fibrin or globules, retains dextrose for several days. This was proved by the results of the test, which were negative in the former and positive in the latter. The intensity of the color in the second case did not change for several days. The author believes that his results confirm those reported by Lepine and Siebert, according to whom diastases and enzymes of a glycolytic nature exist in the fibrin and globules of the blood, but not in the blood serum.

Treatment of Postoperative Intestinal Paralysis—Loewe and Herbrand show that the intestinal peristalsis is regulated by nervous and hormone actions. In discussing the

treatment they point out that the great number of suggested remedies indicates the absence of an entirely satisfactory one. In view of this fact they resorted to treatment with a posterior pituitary preparation that influences the vascular system and the intestine. They report a number of cases in which they used this preparation with good success. Strictly individualized dosage stimulated the peristalsis and the intestinal evacuation even in the severest cases of intestinal atony, without causing circulatory disturbances or impairing the general condition. The clinical observations on the efficacy of the pituitary preparation were corroborated by roentgenologic studies. In serial roentgenologic examinations it was observed that, a few minutes after the injection of smallest amounts, the peristalsis increased and reached its maximum after from ten to fifteen minutes. The authors reach the conclusion that this posterior pituitary preparation is an excellent remedy for the stimulation of the disturbed peristalsis.

Administration of Vitamin C—Schneider and Widmann describe clinical observations and animal experiments on the basis of which they reach the following conclusions: 1. The therapeutic administration of vitamin C produces, although not regularly, a decrease in the globulin content and an increase in the albumin content of the blood, accompanied by a reduction in the sedimentation speed of the erythrocytes. 2. The vitamin C content of the blood seems to be higher in young persons than in older ones. Studies on the serum do not definitely indicate the presence of a hypovitaminosis. 3. The simultaneous administration of thyrotropic hormone of the pituitary and of vitamin C increases the size and weight of the adrenals, which is due to an increase not in the cortex but in the medullary substance.

Basophilic Cell Infiltration in Neurohypophysis in Hypertensive Conditions—Ahlstrom points out that Cushing observed in eclampsia, essential hypertension, arteriosclerosis and basophil adenomas of the anterior hypophysis a more or less severe invasion of basophilic cells in the neurohypophysis, an invasion that originated in the intermediate lobe and extended into the tissues of the posterior lobe. On the basis of these observations Cushing advanced the theory that this infiltration is the morphologic manifestation of an increased secretion of vasopressive hormones of the posterior hypophysis and that the hormones of the posterior hypophysis are formed in the intermediate lobe and from there are passed into the neurohypophysis, the basophilic cell infiltration would be an increased function of the intermediate part and a manifestation of a neurohypophyseal activation. The author emphasizes that Cushing admits that this interpretation is still only a hypothesis. The author studied this problem on thirty-six patients without hypertension and on twenty-five patients with hypertension. He observed that eighteen of the thirty-six patients without hypertension, that is, 50 per cent, had a basophilic cell infiltration in the neurohypophysis and that the infiltration was quite severe in eight cases (22 per cent). He concludes from this that a basophilic cell invasion may exist in the absence of hypertension. Of the twenty-five patients with hypertension twenty-four or 96 per cent, had a basophilic cell infiltration, but it could be considered rather severe in only fifteen cases, or 60 per cent, and it was really severe in only six cases. The author concludes that the interpretation of the basophilic cell invasion is still obscure, for although the studies on this material corroborated Cushing's claim of an increased neurohypophyseal basophilia in hypertensive conditions they indi-

cated also that considerable basophilic invasion may exist in patients without hypertension and that in patients with hypertension the basophilic invasion may be only slight.

Cevitamic Acid in Treatment of Colitis—Hetényi says that two factors induced him to resort to cevitamic acid in the treatment of severe colitis, namely, the hemostatic effect of cevitamic acid and the observation that the diet of patients with this disease frequently has been deficient in vitamin C. He employed the treatment in seven cases. The patients were given at first daily and later every second day an intravenous injection of 150 mg of cevitamic acid. The author reports the clinical histories of two patients in whom the cevitamic acid proved especially helpful and states that in four other cases the results were likewise good, although not quite as favorable as in the two others. In one case the treatment was ineffective.

- *Diuretic Action of Smoking of Tobacco A. Wenusch and R. Schöller—p. 1336

Aminopyrine in Treatment of Residual Hematuria—Hitzberger says that, since Eppinger and his collaborators demonstrated that aminopyrine reduces the permeability of the membranes, he decided to use it in the treatment of post-nephritic hematuria, reasoning that the usual explanation of the etiology of this form of hematuria makes this action of aminopyrine seem desirable. It is generally believed that the glomerular capillaries become impaired by a deficiency in blood perfusion and that, when the blood returns, some erythrocytes pass the capillary membrane and enter the urine. The author describes the clinical histories of six patients with postnephritic hematuria, in whom medication with aminopyrine (from 1.5 to 3 Gm daily) either reduced the hematuria considerably or counteracted it entirely.

Case of Superfetation—Süssi points out that the question of the possibility of superfetation has been frequently the subject of discussions. After citing the opinions of Galen, Hippocrates, Aristotle and Pliny, he shows that, on the basis of present-day knowledge, the possibility of a superfetation depends on the possibility of an ovulation during pregnancy, and recent biologic experiments have proved this possibility. To be sure there still remains the question of nidation. After discussing the various factors that enter into the problem of nidation during an existing pregnancy, the author reports a case that he considers a true superfetation. A primipara, aged 32, gave birth to a full-term boy and twenty minutes later to a living female fetus of about the sixth fetal month. The woman stated that she had had only two cohabitations, the first about twenty days after the last menstruation and the second approximately five months before delivery. There was a great difference in the sizes and in the weights of the fetuses, the ratio being about 7:1, and there was also a considerable difference in the two placentas. As further proof that this was not an ordinary twin birth, the author cites the great differences in the roentgenologic aspects of the two fetuses. He reaches the conclusion that this was a true case of superfetation.

Diuretic Action of Smoking—Wenusch and Schöller describe tests on the diuretic action of the smoking of tobacco. Careful attention was paid to all factors that might influence the diuresis. The persons subjected to these tests were given for several days the same amount and the same types of food and drink, and their mode of living was likewise made uniform during the test period. Moreover, the body temperature, the respiratory and pulse frequencies and the blood pressure were carefully controlled. The first tabular report indicates that a considerable diuresis is produced by smoking in persons who are not accustomed to smoking. The second table reveals that in persons who are strongly addicted to smoking, although a

diuretic action is noticeable, it is not as pronounced as in persons who do not smoke at all or who smoke only occasionally. The third table shows that an incipient diuresis turns into the opposite as soon as signs of nicotine intoxication appear. The authors think that the knowledge gained in these tests may attain practical importance if, for instance, persons who are strongly addicted to smoking are suddenly compelled to stop it, as in case of an operation. They think that in these cases the abolishment of this diuretic component should be given consideration and, if necessary, should be compensated by medication.

Ovariectomy in Osteitis Fibrosa Cystica of Parathyroid Origin.—Parhon and Tomorug report the case of a woman, aged 30, whose bones fractured readily and were extremely flexible. There was slow consolidation of the bones after the fractures. Roentgenoscopy disclosed calcium deficiency of the hip joint, whereas the examination of the blood revealed increased calcium content. The condition was diagnosed as osteitis fibrosa cystica, or, on the basis of Lievre's terminology, as parathyroid osteosis. The patient was given calcium, epinephrine and ultraviolet irradiations, and after that the consolidation of the fractured bones was somewhat better. Later the patient consented to a bilateral ovariectomy, which had been suggested to her previously. One of the ovaries was found to be twice the size of a normal ovary. After this intervention the patient felt at first extremely weak, but later the condition of the vertebral column did not become further exacerbated, the patient felt better and suffered no more fractures, and her movements were considerably freer. Roentgenoscopy of the bones of the arms disclosed deformities of the diaphyses and swellings at the ends. At these sites the normal structure of the bones was replaced by cystic formations. The epiphyses of these bones were thickened and less dense. The same change was present also on the upper end of the femur. Roentgenoscopy of the skull disclosed considerable thickening of the temporal and frontal bones, thinning of the walls of the sella turcica and a lengthening and deepening of the sella. Examination of the parietal bones revealed nodules, the center of which had increased calcium content. The authors are convinced that this is a case of osteitis fibrosa cystica of parathyroid origin. Although they do not recommend ovariectomy for all women with this disorder, they emphasize that in this case ovariectomy resulted in a considerable improvement. They stress that the parathyroids are not the only glands that are involved in the calcium metabolism and think that the ovaries, the thyroid, the hypophysis, the adrenals and perhaps still other organs play a part. They think that the ovaries might play a part in the decalcification of the bones and in the elimination of the calcium from the organism. This would explain the renewed calcium deposit following their removal. The calcium content of the blood was reduced following the castration.

Roentgen Treatment of Patients with Hodgkin's Disease.—Schwarz emphasizes that there are two procedures to be avoided in the roentgen therapy of Hodgkin's disease, namely, the application of a large single dose to a circumscribed field and total irradiation with a large dose. In discussing how roentgen therapy of Hodgkin's disease should be done the author gives the following general rules: 1. Each focus should be irradiated. 2. Irradiation should be done in the fractional manner at one or two day intervals. 3. The sizes of the fields should not exceed 800 sq. cm., that is, they should be about 24 by 30, 18 by 40 and so on. 4. The focal doses should be 50, 80 or at the most 100 roentgens, which

implies that the surface doses should not exceed 250 roentgens. 5. The tolerance of the skin, the status of the blood and the general reaction (nausea, fever) should be watched. 6. The patient should be kept under constant control for the appearance of new foci. The author illustrates with case histories that the ray sensitivity of lymphogranulomatous formations differs greatly. He says that he saw a mediastinal tumor disappear shortly after the fractional application of a total focal dose of 600 roentgens, whereas in other cases mediastinal tumors required total focal doses of 2,000 roentgens. The heart of the patient should as much as possible be excluded from the irradiation. The difference in ray sensitivity and other factors indicate that the roentgen treatment of Hodgkin's disease cannot be done according to rigid rules, but that individualization is necessary. The treatment must take account not only of the course of the disease, that is, whether it is acute, subacute or chronic, but also of the localization of the glandular swellings. The severity of the roentgen intoxication differs greatly in the individual patients. However, it has been found that intravenous as well as oral liver therapy reduces the severity of the symptoms of intoxication. It is further pointed out that, if the foci of lymphogranulomatosis become "refractory" in the course of prolonged roentgen treatment, the torpidity can be counteracted by the intravenous administration of thorium X. This radioactive substance emits alpha rays. Since it is well known that one type of rays sensitizes to another type, the combined administration of roentgen rays and of radioactive thorium seems advisable in some cases. In the conclusion the author points out that there are two factors which are especially detrimental to patients with Hodgkin's disease: pregnancy and the climate at high altitudes. Since these factors are likely to cause rapid progress of the disease or the generalization of the formerly localized process, they must be avoided in patients with Hodgkin's disease.

Cause of Death in Intestinal Occlusion.—Starlinger and Scholl state that observations on more than 250 necroscopically corroborated cases of intestinal occlusion indicate that peritonitis is the cause of most fatalities in intestinal occlusion, pneumonia and circulatory failure being the other chief causes. In the last analysis, even the fatal outcome of peritonitis is really a circulatory collapse. They show that uncomplicated intestinal occlusion, which as yet has caused neither peritonitis nor destruction of the intestinal wall, is accompanied by a severe disturbance in the intermediate and sodium chloride metabolism, which in turn are partly the result of a severe hepatic impairment and lead to severe dehydration of the tissues. Thus there develops an inspissation of the blood, a capillary stasis, a continuous decrease in the amount of the circulating blood and a failure of the so-called venopressor mechanism, which plays an important part in the maintenance of the circulation. Following a description of observations on dogs, the authors conclude that the failure of the circulation is the chief cause of death in intestinal occlusion. In accordance with this knowledge they advise early surgical treatment, which should aim at the smallest possible intervention. Moreover, attempts should be made to counteract the metabolic disturbances, to promote the hepatic function and to support the circulation. They advise that sodium chloride be administered in the form of hypertonic solutions, 5 per cent solutions of dextrose together with small quantities of insulin and blood transfusions. If peritonitis has already developed, peritonitis serum should be administered. To stimulate diaphragmatic respiration and the circulation, carbon dioxide should be given in carefully adjusted doses. As soon as the intestinal obstruction has been counteracted peristalsis should be stimulated.

Blood Transfusion During Childhood—Schäffer points out that the indications for blood transfusion become steadily more numerous. He says that until three years ago his clinic employed chiefly citrated blood, but since then native blood has been transfused by means of Lampert's amber apparatus. He considers from 10 to 12 cc of blood per kilogram of weight the minimum to be given in children and says that this quantity can be increased up to 30 cc. and, in exceptional cases, even up to 40 cc. The author considers the various forms of anemia the chief indication for blood transfusions. In blood tests performed in children with anemia, he found that the erythrocytes and the hemoglobin content showed a considerable increase immediately after the transfusion. This high level was maintained for from two to three days, but after that there was a decrease, particularly in the number of erythrocytes. Between the twelfth and eighteenth days the erythrocytes sometimes reached the pretransfusion values, but after that there was again an increase, which continued for several weeks and at the end of which the values were like those immediately after the transfusion or even higher. Nurshings were an exception to this rule in that this process took a more rapid course. In septic conditions the erythrocytes showed a different behavior from that in anemia, but when the transfusion was done early there was a favorable influence on the disease process. The results of blood transfusions were not satisfactory in tuberculosis of the bones. The author cites four cases in which citrated blood was used and in which complications developed. However, although no complications arose in the large number of cases in which native blood was given, the author thinks that the complications cannot be entirely ascribed to the citrated blood.

Treatment of Meningitides with Derivatives of Pyrazolon E. Risak.—p. 583

Splenectomy in Treatment of Varicose Hemorrhages in Cirrhosis of Liver—Mandel and Marcus point out that hemorrhages from varices in the stomach and esophagus, which develop after circulatory disturbances in the region of the portal vein, have been treated with extirpation of the spleen. Such varices develop in circumscribed and in general stasis. They represent the collateral channels of the portal vein. Thus they are always present in cases of thrombosis of the splenic vein and consequently this disturbance is characterized by severe gastro-intestinal hemorrhages. The literature reports a number of cases of thrombosis of the splenic vein in which splenectomy was done with good results. Splenectomy has been recommended also for the varices that develop in the course of cirrhosis of the liver. If it is assumed that the development of varices in cirrhosis of the liver is at least partly caused by the chronic generalized stasis of the portal vein it seems natural to assume that an eventual favorable effect of splenectomy is to be found in hemodynamic factors like those that exist in thrombosis of the splenic vein, that is, in a localized stasis. However, an influence on the varices of the stomach and of the esophagus is conceivable only if there exist connections between the splenic vein and the varices of the esophagus and stomach. For this reason the authors decided to study the anatomy of this venous region. After mentioning the connections that normally exist between the esophageal veins and the splenic vein, they point out that these anastomoses, which normally are extremely fine, become dilated and tortuous when they become collaterals in case of cirrhosis. They describe their observations in four cases of cirrhosis of the liver. Then they point out that, in addition to the clarification of the anatomic conditions, the direction of the blood currents in this venous region is important. They are convinced that the cur-

rents in this region are dependent on many different pressure fluctuations, the more so since the branches of the portal vein are without valves. If the flow through the liver is inhibited by a cirrhotic process, the splenic blood passes through the collateral channels in the region of the stomach and the esophagus. Thus, if splenectomy is done, a large portion of the blood that passes through the varices is eliminated, and the veins of the mucous membrane are relieved of some of their load. Moreover, it is possible that the removal of the spleen changes the pressure conditions in the splenic vein and its collaterals in such a manner that blood from gastro-intestinal veins, which normally would enter the portal vein, passes by way of the stump of the lienal vein and its anastomoses into the region of the cava inferior. The authors were able to demonstrate such connections in all cases. Theoretical reasoning permits the conclusion that splenectomy reduces the load of the varices and thus also the danger of hemorrhage.

Diagnostic Errors in Diseases of Organs of Nutrition Role of Roentgen Study in Some O. O. Den—p. 1277
Gastric Duodenal Ulcer in Children A. Ya. Dukhanov—p. 1289

Roentgen Diagnosis of Chronic Gastritis—To bring out the mucosa in the stomach, Reinberg advises introduction of small amounts of a thin watery suspension of barium sulfate. It does not provoke secretion of gastric juice. He advises emptying of the stomach just before the examination. Manual palpation of the stomach assists in the distribution of the contrast material. Fluoroscopy is to be followed by the taking of serial films. The roentgen diagnosis of chronic gastritis lags far behind the excellent results obtained with the roentgen diagnosis of gastric and duodenal ulceration and tumors of the stomach. Chronic gastritis is not a definite clinical picture but a symptom complex. Gastrosopic or gastrophotographic control of roentgen diagnosis of chronic gastritis reveals a percentage of correct diagnoses between 20 and 50 per cent, as given by various authors. The borderline between the normal and the pathologic appearance of the gastric mucosa has not been clearly determined. The hypertrophic form of gastritis is more readily demonstrable than the atrophic. The increase in the caliber of the folds is of significance only when the furrows between them are widened. This is accompanied by a diminution in the number of the folds so that instead of four or five, there may be two or three thick prominent ridges. Atrophic gastritis, on the contrary, is made manifest by the formation of a delicate relief with a decrease in the height and width of the folds and an increase in the width of the furrows. Particularly valuable for the diagnosis is the rigidity of the folds on palpation as contrasted with the elastic "autoplastic" behavior of the normal gastric mucosa. The persistence of these signs on a repeated roentgenologic examination has a determining value in arriving at the diagnosis of chronic gastritis. High grade edema of the mucosa and the submucosa is readily visualized in the film. Elevation of the mucous membrane, the size of a pea, is likewise recognizable in the film. In the author's experience, gastro-enterostomy is regularly followed by a chronic gastritis, which appears soon after the operation and may persist for years. The notion that hypertrophic gastritis is accompanied by hypersecretion and hyperacidity, while the atrophic form is accompanied by hyposecretion and hypo-acidity, is not correct. It appears that changes in the secretory function are not determined by the anatomic picture. Pyloric gastritis and diffuse gastritis are, as a rule, associated with a duodenitis and, not infrequently, with an enteritis of the adjacent small intestine. The author concludes that the roentgenologic diagnosis of chronic gastritis is a harmless, physiologic, practical method, the principal fault of which lies in its inability to recognize all the cases of gastritis. The common error is to include normal appearances among the pathologic.

MODERN CONCEPTS OF ROENTGEN THERAPY IN CANCER

W EDWARD CHAMBERLAIN, MD
PHILADELPHIA

Roentgen discovered the α -rays in November 1895.¹ The news reached the world of science and medicine in January 1896. In an incredibly short time physicians all over the world, oblivious to the possible biologic effects of the new ray, were using it in diagnosis. It soon became apparent that the penetration of the rays through living tissue was not without harmful potentialities and biologic effects.

Haphazard attempts to use the α -rays therapeutically in 1896-1897 were of little significance and were but gropings in the dark. The earliest announcements (1897-1898) of proved therapeutic value, based on scientific observation, concerned diseases of the skin. Applications to malignant disease probably date from the reports of Sjogren,² Stenbeck,³ and Pusey.⁴

The development of roentgen therapy to its present state of relative enlightenment has been immeasurably aided by the excellent work of physicists and engineers. They have made advances technically possible. Nevertheless it must be pointed out that the greatest barriers that have been surmounted have been in the strictly biologic field. This is important, for there has been, from the very beginning, an unfortunate tendency to treat each purely technical advance as of inherent value to the cancer patient. Every time a new tube stand or a slimmer control panel comes from the apparatus manufacturer, some one is sure to acclaim it as of fundamental worth. Yet there has never been a period in the history of roentgen therapy when the potentialities actually at hand were used with complete intelligence and thorough application of all proved facts. It is necessary to stress this point in order to review intelligently the history of this therapeutic modality. Had the roentgen therapist of 1910-1918 made full use of available knowledge, the mistaken ideas of 1918-1924 would not have had their vogue. Today, as one reads the sometimes unconservative accounts of treatment with α -ray tubes operating at voltages of the order of a million, one may ask oneself whether the voltage

applied to the α -ray tube is not of minor importance in comparison with the selection of the proper technic for the individual cancer problem.

At the close of the war, in November 1918, there came out of Germany a series of announcements suggesting that the increase of the voltage factor to 200,000, and the increase of filtration made possible by the use of such voltages, had revolutionized the art by substituting "cancer killing" for "treating patients." That the overenthusiasm of 1919-1924 was unjustified is now well known. That tumor regressions were observed with greater regularity than with older technics cannot be denied. The mistake was in ascribing the change to the increase of voltage and filter when the chief alteration of technic was in the size of the dose delivered. In other words, at the moment of change-over from 135,000 volts to 200,000 volts, and from aluminum to copper filters, very significant changes were made in the size of the total dose, the distance of the patient from the tube and the periodicity of treatments. Most radiologists now recognize the fact that the voltage factor, long believed to be the most important, was actually one of the least important factors changed at that time.

As soon as it was discovered that the so-called deep therapy of 1919 produced a pitifully small percentage of "cures" of deep seated cancer, overenthusiasm gave way to unwarranted skepticism. It became customary to doubt the original diagnosis in every case of apparent cure. However, in the ten years between 1918 and 1928 the real foundations for present roentgen therapy were laid. First came the physicists, with accurate methods of measurement under standardizable and reproducible conditions. For the first time it became possible for physicians in various parts of the world to describe their dosage and quality factors in terms of the centimeter-gram-second system of international physical units. This important advance paved the way for the work of the research biologist, who brought forth scientific data regarding the effects of measured amounts and specified qualities of α -rays on standardized biologic material.

The history of roentgen therapy in cancer from the beginning down to the present day may be tabulated about as follows:

1896-1903, gropings, discovery that tumor regression could sometimes be produced.

1903-1906, optimism based on wishful thinking and ignorance of inherent limitations.

1906-1910, fear of roentgen injuries and natural discouragement, which paved the way for.

1910-1918 first period of disrepute, characterized by unwarranted skepticism and courageous perseverance by a few pioneer spirits.

1918-1924, optimism based on the mistaken idea that the increase of voltage from 135,000 to 200,000 had introduced revolutionary changes in the possibility of cure.

1924-1928, second period of disrepute, during which scientific investigators continued to lay the foundations for 1928-?, the period of healthy growth, steady progress in refinement of technic, scientific evaluation of the method

If the star of roentgen therapy wanes again it will be because a brighter star has risen to outshine it, not because the present use of the method is founded on wrong concepts or unjustified optimism. It is recognized today that, in spite of thousands of cures and countless valuable palliations, irradiation, like surgery, is not the final answer to the cancer problem. Realization of this fact does not interfere with continued progress. It should shield one, however, from the mistake of ascribing revolutionary virtue to the interesting technical changes that loom so large on the present-day horizon.

LIMITATIONS OF THE METHOD

The scientific roentgenologist of today recognizes certain limitations inherent in his method.

1 The tumor he is treating is surrounded by and intimately associated with normal tissues, the integrity

Survival and mortality curve for Flexner rat carcinoma exposed to varying doses of x-rays (after Charles Packard). As much as 800 roentgens failed to influence survival (subthreshold). 10 per cent of the tumor cells were killed by 1450 roentgens, 50 per cent by 1950 roentgens and approximately 1 per cent survived doses as high as 3500 roentgens.

of which must be preserved. The tolerance of these normal tissues is often not sufficient to permit him to use a large enough dose to cure the cancer. Some progress has been made toward overcoming this limitation, particularly by fractionating the dose,⁵ but there are reasons for believing that this will always remain an important limiting factor.

2 Amounts of radiation that are sufficient to rid the patient of from 90 to 99 per cent of his tumor cells may not have any permanent deleterious effect on the remainder, as shown in the illustration. One of the fundamental laws of biologic effects of irradiation is involved in this inherent limitation.⁶

5 Coutard Henri. Principles of X-Ray Therapy of Malignant Diseases. *Lancet* 2:1 (July 7) 1934. Forasell Gosta. Radiotherapy of Malignant Tumours in Sweden. *Brit J Radiol* 3:198 (May) 1930. Regaud C. Sur les principes radiophysiques de la radiothérapie des cancers. *Acta radiol* 11:455 1930.

6 Packard Charles. Biologic Effects of Roentgen Rays and Radium in the Science of Radiology.

3 Seemingly uncontrollable factors are involved. When cures are obtained the dose has frequently been less than would have been necessary for an actual destruction of all the cells of the cancer. Factors other than a direct lethal effect on the tumor must have been operative. One of these factors may be in some way involved in the fibrosis that sometimes follows irradiation. Viable cancer cells may remain for many years in the tissues of a clinically cured carcinoma patient. This accounts for the occasional, very disturbing late recurrence after apparent radiologic cure. The indications for coping with this factor are not clear. At first glance it might appear that surgical removal of the involved organ or tumor bed should follow, as a routine, the production of an apparent cure by irradiation. The trouble with this is that when the original tumor was inoperable there is a great likelihood that the subsequent surgery will cut through some of the encapsulated collections of arrested but viable tumor cells, with resultant disastrous recurrence. It is often safer to "let sleeping dogs lie," though in doing so one may be leaving the sword of Damocles over the patient's head.

4 After irradiation has been extensively used in a given case, whether efficiently or inefficiently, the response of that case to subsequent irradiation may be very disappointing. In a certain percentage of cases a thorough trial of irradiation may close the door to all known forms of therapy, both surgical and radiologic. The reasons for this are not well understood.

5 Like the surgeon, the radiologist suffers the limitation that he is frequently unable to foretell the result of his therapy. Actually his dilemma is greater than the surgeon's, for the latter's is concerned with the location, size and distribution of the tumor, factors that admit of a certain degree of analysis. The corresponding factors for the radiologist, on the other hand, are susceptibility of the tumor cells and certain intangible factors that may be grouped under the general term of the reaction of the patient's tissues. This inability to foretell the outcome in a given case operates as a practical limitation, for it tends to preserve an unfortunate suggestion of experimentation, leading one to advise surgery even in cases that might be treated better by irradiation.

RECENT ADVANCES

In spite of a better knowledge of the limitations of the method, roentgen therapy is being used more extensively today than at any previous time. This fact alone is sufficient evidence that the method has proved merit, for the present vogue is based not on superstition or wishful thinking but on sound knowledge and proved fact. Improvements in apparatus, while immensely valuable, have had small part in promoting this increasing use of irradiation. The important advances have been in the knowledge of how best to divide the dose, how best to preserve the integrity of the normal tissues, and how large a total dose to administer in a given case. These are the advances that deserve attention at this point.

1 *New Knowledge of the Nature and Degree of Skin Tolerance and the Recovery of the Skin After Irradiation*.—Looking back fifteen years, I am surprised that it has taken so long to uncover the facts regarding the nature and rate of recovery of the skin from the immediate effects of irradiation. Fear of permanent damage was undoubtedly the chief cause of the delay, but the simplicity of the methods that finally opened the eyes of the profession leads one to wish

that the superstitions of yesteryear had been dissipated sooner. Only a short time ago radiologists were practically in agreement that skin recovery from the immediate effects of fractional doses of 200 kilovolt, copper-filtered x-rays took place at a rate of from 5 to 9 per cent daily and that this recovery rate could be expressed by a fairly simple logarithmic curve. Through the work of Duffy, Arneson and Voke,⁷ presaged by the courageous experiments of Coutard,⁸ it is now known that recovery may be as high as from 60 to 70 per cent during the first twenty-four hours after a first exposure and from 70 to 80 per cent during the first forty-eight hours. Expressed in terms of practical units, this means that a year ago it was believed that two 400 roentgen doses, twenty-four hours apart, would produce the same effect on the skin as a single dose of about 750 roentgens, it is now known that such a series results in a skin effect equivalent to that produced by a single dose of about 525 roentgens.

2 Increasing Knowledge of the Relationship Between the Location, Type and Microscopic Appearance of the Tumor and the Most Effective Method of Applying the Irradiation—In this matter the profession is on the very frontier of progress. Many experienced radiologists are as yet not fully aware of the full significance of this and related studies. Because Coutard and others have shown that protracted fractional daily dosage will produce a hundred times as many five-year cures of pharyngeal and laryngeal cancer as will any single-dose technic, there is an unwarranted tendency to treat every tumor after the method of Coutard. Unless the rate of recovery from the effects of radiation is slower in the tumor than in the normal tissues, including the skin, protracted daily fractionation is valueless or even inferior. Present indications are that clinical experience plus a proper attention to the microscopic appearance of the biopsy specimen may lead to a definite improvement in results through more and more individualization in the selection of the treatment technic. I have had the experience of obtaining a three year cure in a case of lymphosarcoma of the tonsil treated by a short intensive three-day series, after a protracted fractional method had produced only partial regression, with rapid recurrence during the tenth week after the end of the first treatment series.

Authorities in the field of radiation therapy have always preached individualization. A scientific basis for such individualization is now being set up. As a further example of what may be expected in this field, one may point to the varying effects of different technics on the vascular elements in the irradiated tissue. The arterioles and capillaries are apparently able to recover very well from the effects of a Coutard series, from 100 to 200 roentgens per day, for example, with a total dose in the neighborhood of 3,000 roentgens, a considerably smaller total dose may produce disturbing avascularity if delivered in 500 roentgen fractions at intervals of the order of one month. Ginsburg⁹ showed

in 1927 that the skeletal metastases of certain very radiation-resistant thyroid adenomas may respond favorably to the fourth or fifth monthly series, though apparently quite refractory to a single series of any type. It is reasonable to believe that such results are due to a favorable diminution in the blood supply of the tumor, the tumor itself being too resistant to respond directly to the irradiation. Some believe that, when knowledge is more complete, some tumors will be attacked by single massive doses, some by the protracted fractional dose method of Coutard and still others by special technics yet to be worked out.

3 Increasing Appreciation of the Place of Preoperative Irradiation—That preoperative irradiation is still in its experimental stages, few will deny. Perhaps it is still too soon to include it as one of the important advances in the present state of our knowledge. Nevertheless, the method is growing rapidly in favor of the surgeon and there is evidence that its use is beginning to rest on a scientific basis. For example, the benefits to be derived from preoperative irradiation are minimal when the operation follows immediately or very soon after the irradiation and are maximal when thorough irradiation is followed by a sufficient delay for tumor regression to become maximal. The ability to draw such conclusions is argument for the thesis that preoperative irradiation is entering on a scientific phase, even though it is not yet known exactly how much effect it will have on the five-year cure statistics.

4 Decreasing Emphasis on Postoperative Irradiation—The routine employment of postoperative irradiation has always rested on unscientific thinking. Too often the wish has been father to the thought. It may comfort the patient or his family to hear the surgeon say "There now, I have removed practically all of the cancer. If I have left a few cancer cells, the radiologist can take care of them with a shotgun dose of x-rays." To the thinking radiologist it has often seemed that since radiologic cure rests on tumor cell sensitivity and tissue response to irradiation rather than on the numerical count of tumor cells, the radiologist who can "take care of the residual tumor cells" after a surgical operation might have taken equally good care of the entire tumor, especially in view of the fact that his aim is better and his therapy less hindered when he is treating a tangible tumor, not an intangible ghost. I am not advocating the complete scuttling of all forms of postoperative irradiation in every case. Neither am I advocating the abandonment of surgery in favor of irradiation in carcinoma. I do feel, however, that the decreasing emphasis on routine postoperative irradiation is evidence of progress, toward the substitution of correct thinking for poorly founded superstition.

UNSOLVED PROBLEMS FOR THE FUTURE

1 Will the Use of Higher Voltages and Thicker Filters (i. e., Shorter Wavelengths) Increase the Percentage of Five-Year Cures?—Not long ago, physicists were fairly unanimous in the opinion that the only benefits to be derived from shortening the wavelength, so far as cancer therapy is concerned, are envisaged in the possible increase of the penetration (percentage depth dose). They had ascertained that the increased penetration through metals, obtainable by the use of supervoltages and thicker primary filters, was not accompanied by increased penetration through tissue, beyond a certain easily reached point. Avoiding complicated data and mathematical analyses, one may

sum up their observations about as follows "Desired increases of the percentage depth dose can be obtained by increase of the distance between patient and x-ray tube and by elaboration of the principle of 'cross-fire' We are already operating with percentage depth doses near the maximum obtainable in the animal body The degradation of the x-ray beam (synonyms 'softening,' 'increase of wavelength') through Compton effect becomes such a large factor at higher voltages that the gain is little or nothing In short, there is no physical basis for undertaking to treat patients with costly and troublesome million-volt x-ray apparatus"

Such analyses as the foregoing are valuable but incomplete Before one is justified in deciding that nothing is to be gained by the use of extremely high voltages, certain additional questions must be answered 1 X-ray beams generated at voltages of a million or so may not differ markedly in penetrating power from conventional present day x-ray beams, but they ionize the atoms in the irradiated tissue according to a definitely different pattern Is this significant? 2 Irradiation at "supervoltages" includes bombardment of the tissues with neutrons, highly penetrating particles which are practically absent from conventional present-day x-ray beams May these not prove to be of some value or are they wholly valueless or even harmful? 3 Some of the radiologists who have had a wide experience with external irradiation by both x-rays and radioactive substances are of the opinion that gamma rays are superior to x-rays for the treatment of cancer This has by no means been proved, but if it is so it is not because of any superiority in penetration, expressed in terms of the percentage depth dose As a matter of fact, no radiologist in the world today has sufficient radium at his command to permit a practical technic at depth doses as great as are readily attained with conventional x-ray beams Assuming that gamma rays are actually more efficacious than the x-rays in cancer therapy, it would follow that in spite of an inferior percentage depth dose the gamma ray beam has a greater specificity for the tumor cells, i e., damages the tumor cells more, the normal tissues less If this belief in a demonstrable superiority of gamma rays is superstition, as some believe, there is little reason to think that "million volt x-rays" will prove superior to present-day practice But suppose it turns out otherwise The question must remain, for the present, unanswered

2 *Can Surgery Prevent the Late Recurrences of Tumors That Have Apparently Completely Regressed?*—Perhaps, before enough years have passed for this question to be answered, the real and final answer to the cancer problem will have been given In the meantime one can only plead for complete records and honest analyses of the results of various combinations of irradiation and surgery For the present, this question must also remain unanswered

CONCLUSION

Modern concepts of roentgen therapy in cancer do not permit one to continue any fancied rivalry of twenty years ago between radiation therapy and surgery Today the radiologist and the surgeon stand face to face, each in need of the other's help, each ready to do his proper share of the work of combating cancer¹⁰ The radiologist is just as anxious to avoid taking human life by depriving a patient of the benefits of properly

indicated surgery as the surgeon is anxious to avoid the futile mutilation of a patient who might better be treated by irradiation Their brotherhood is made more complete by their common knowledge that neither has the final answer to the cancer problem that real cooperation between physician, surgeon, pathologist and radiologist constitutes the best armamentarium in the present-day battle with cancer

3401 North Broad Street

ETIOLOGY OF CANCER

A PARTIAL REVIEW

LLOYD F CRAVER, MD
NEW YORK

Modern pathology reveals that cancer is not a single disease but a multitude of different diseases and that the boundary between malignant and benign is not everywhere sharply defined Not much can be said about that aspect of the etiology of cancer which has to do with the fundamental nature of the disease, for that is bound up with the very nature of the growth process itself, about which little is known Therefore this paper will be restricted chiefly to a consideration of those extraneous factors which may act on cells and tissues in such a way as to produce cancer

The multiplicity of the cancer process is indicated not only by its widely varying forms but also by the great number of factors that have already been discovered to be capable of affecting tissues, apparently previously normal or predisposed by some anatomic variation, and inciting them to form malignant tumors Cohnheim's theory accounts for the source of certain tumors, but the great majority may be attributed to the effects of chronic irritation on adult tissues

That cancer in man is not a germ or virus disease is the accepted belief of all competent students of the problem That diet has any general relation to the etiology of cancer may safely be denied, nor does it appear likely that the excess or deficiency of any one chemical substance, hormone, or vitamin will be found to be a universal "cause of cancer" This is not to be taken to deny that in specific organs or tissues, under certain conditions, diet, chemicals or hormones may be important contributing or even more direct etiologic factors

Syphilis probably does not foster the development of cancer in any general sense but only in certain locations, such as the tongue, where syphilitic glossitis and leukoplakia may form the basis for multiple carcinomas

Tuberculosis was formerly believed to offer a certain antagonism to cancer Yet there is a good percentage of cases of epithelioma on the basis of lupus, and cancer of the lung may develop in the walls of tuberculous cavities Tuberculosis is a fairly common complication in cancer patients

In a recent paper on the relation of trauma to malignant tumors Ewing¹ has reaffirmed the teaching that a single trauma of normal tissues is incapable of producing a malignant tumor He grants that trauma may

be an important indirect determining cause of certain tumors but in such cases finds that additional factors, such as delayed healing, infection, chronic irritation and probably hereditary and local predisposition, are at work. The production of tumors in experimental animals by trauma occurs only under special conditions of inherited or induced susceptibility, quite without parallel in man. Strict adherence to the criteria emphasized by Ewing successfully nullifies practically all claims of traumatic cancer in man.

AGE AND SEX

Pack's² study of age and sex distribution and incidence of nearly 20,000 tumors showed that the risk of certain tumors developing at various ages is different from what is popularly supposed. For example, the incidence of sarcoma of various kinds differs only slightly from age 20 to age 80, when one takes into account the numbers of persons actually living at different ages.

HEREDITY

While, in general, cancer in man does not appear to be influenced by a genetic factor, there are particular types of tumors that undoubtedly have a hereditary basis, such as neurofibromatosis, entailing a certain risk of neurogenic sarcoma, gliomas of the retina, multiple skin cancer on the basis of xeroderma pigmentosum, osteogenic sarcoma on the basis of multiple enchondromas and exostoses.

A history of the occurrence of cancer more frequently in families of cancer patients is usually interpreted as indicating a combination of factors such as age, occupation, habits, and anatomic or physiologic peculiarities, rather than a true inheritance of susceptibility or resistance to cancer.

Lacassagne³ has shown recently that the development of mammary cancer in mice treated by injections of estrogenic substance is dependent on a hereditary factor determining the susceptibility of the breast to estrogenic substance.

Slye's work on heredity of various tumors in mice is usually looked on as having little importance in regard to human cancer.

Certain observations on the occurrence of cancer in human twins are of interest at this point. It has been noted that, when a tumor occurs in one of a pair of homologous twins, in a high proportion of cases the other member of the pair develops, at about the same age, a tumor which in general is of the same type, in the same organ, or in an ontogenetically related organ. Murphy⁴ looks on these observations as speaking strongly in favor of a genetic control, while Versluys⁵ concludes that, except for determining the site, hereditary factors play a very small role in the development of tumors.

IRRITANTS

A long list of agents of different classes has been demonstrated however, to be definitely capable of acting on tissues to cause chronic irritation or growth stimulus in such a way as to produce cancer.

In the electromagnetic spectrum all wavelengths lying in the range between heat, near one extreme, and gamma rays, near the other extreme, are found to cause chronic tissue reactions that may eventuate in malignant tumors. Repeated exposure of the skin to heat, as in wearers of the kangri box in India or the kairo box in Japan, in iron molders or in English locomotive firemen, may produce a chronic dermatitis that forms the basis for epithelioma. A single burn sufficient to leave a scar, particularly in areas in which the scar is subjected to repeated fissuring or trauma, may eventually lead to cancer of the skin. The age of the scar is more important than the age of the patient. Hot pipe stems may cause cancer of the lip. A habit of drinking hot tea may be responsible for cancer of the esophagus in some cases.

Sunlight has been shown to be a causative factor in cancer of the exposed parts of the skin, as in sailors and farmers. In Australia, Molesworth⁶ finds that cutaneous cancer is more common in the white race and in the albino natives. The ultraviolet rays may be mainly responsible, but Carozzi⁷ believes that the visible spectrum may be injurious. The carcinogenic action of sunlight is startlingly evident in xeroderma pigmentosum. In certain cases of melanoma, sunlight has apparently been the chief irritant of a mole. A protruding lower lip is liable to sunburn and may thus be more likely to develop epithelioma. Epithelioma of the skin of animals has been produced by exposures to ultraviolet rays.

The role in carcinogenesis of the Gurwitsch mitogenic rays lying in the ultraviolet band from about 1,900 to 2,400 angstrom units is still largely speculative. Cancer of the skin resulting from radiodermatitis, particularly on the hands of pioneer roentgenologists and radium therapists, is only too well known. Radiation cancer is also seen frequently as a result of overenthusiastic superficial irradiation as for psoriasis, pruritus ani and facial hypertrichosis. Sarcomas have been produced in experimental animals by exposing them to x-rays.

A new etiology for bone sarcoma in man appeared in dramatic fashion in the painters of radium dials, who, by moistening their brushes in their mouths, ingested appreciable amounts of radium and mesothorium. These substances were deposited, similarly to lead, in the bones, which then became subjected to a ceaseless bombardment from within, chiefly by alpha particles. Those who survived the earlier effects, anemia and necrosis of the jaws, were doomed to die years later of osteogenic sarcoma. The Schneeberg and Joachimstal cancer of the lungs in miners is now attributed mainly to the inhalation of emanations of radioactive minerals.

Animal parasites lead in man and lower animals to a variety of chronic irritations that produce cancer. Bilharzia infestation of the bladder is known to be followed by cancer of that organ in a good proportion of cases. Ewing has found trichinae in a number of cancerous tongues. Fibiger demonstrated that spiroptera carried by cockroaches were responsible for carcinoma in the stomach of rats. Several other kinds of parasites have been found associated with tumors of lower animals.

Chemicals—Since the recognition of chimney sweeps' cancer by Percival Pott in 1820, a long list of chemical

irritants has been gradually accumulated, the effects of which have been noted chiefly on the skin of man clinically, or in the laboratory on the skin of animals. Scarlet red and other lipid solvents of the aniline series, fats, fatty and mineral acids, indole and skatole fall into this category. The prolonged administration of arsenic may be followed after several or many years by a pathognomonic type of multiple warty keratoses of the palms and soles, and multiple keratoses elsewhere on the skin, a condition which not infrequently serves as the basis for multiple epitheliomas. Arsenic has been suspected also of being cancerigenic in tissues other than the skin, for example, in the lungs of the Schneeberg miners.

In the aniline industry, in workers with the intermediate products and derivatives of benzene, toluene, xylene, naphthalene, anthracene and phenanthrene, there is an incidence of cancer of the bladder of from 4 to 5 per cent. These tumors may appear at any time after two years of exposure. In many cases the tumors are multiple, and studies of pathogenesis suggest that the compounds are absorbed mainly through the respiratory tract and may affect the basal layers of the mucous membrane of the bladder through circulation in the terminal capillaries. According to Ferguson,⁸ all efforts to demonstrate carcinogenic agents in the urine of aniline workers have failed. The compounds that are believed to be responsible are aniline, alpha and beta naphthylamine, and benzidine.

Janssen⁹ reports the occurrence of cancer of the bladder in patients who had been treated with tar over long periods for psoriasis.

A vast amount of experimental work has followed the discovery by Yamagiwa and Ichikawa in 1915 that cancer could be produced in the skin of rabbits' ears by applying tar. Many of the higher distillation components of tar, which have been found to be the agents responsible for its carcinogenic properties, have been chemically isolated, identified and prepared synthetically. Loeb¹⁰ has named seven of the principal carcinogenic hydrocarbons, and he states that in general a molecular structure consisting of rings attached to the 1, 2 and 5, 6 position of the anthracene ring system tends to induce a marked carcinogenic activity.

These agents apparently produce cancer by acting on normal cells, as stimulants of growth, and need not cause local irritation. Evidence has been adduced to show that a general, possibly specific, intoxication of the animals plays a part in the production of cancer by tar derivatives.

RELATION OF TAR DERIVATIVES TO HORMONES AND STEROLS

One of the most interesting recent developments, and perhaps one of epochal importance, is the recognition of the fact that these carcinogenic hydrocarbons are closely related by chemical structure to a series of substances that are of common occurrence in the body and of great importance biologically, namely, bile acids, cholesterol, ergosterol, vitamin D, the testis hormone and particularly the estrus producing and possibly the luteal hormone. This recognition has led naturally

to the suggestion by Kennaway and Cook that under some conditions the sterols normally present in the body might undergo such a chemical alteration as to become carcinogenic. Moreover, it has been found that some of the carcinogenic derivatives of tar are capable of producing estrus in castrated rats and mice. This leads to a consideration of the influence of hormones in carcinogenesis. Choriocarcinoma was attributed years ago by Pick to stimulation of the chorionic cells by excessive secretion of corpus luteum cysts. Early castration of female mice belonging to strains having a known high incidence of mammary cancer reduces the cancer rate to zero or nearly so. Lacassagne has succeeded, by injecting large doses of an estrogenic substance¹¹ in producing mammary cancer in male mice, belonging to the R 3 strain of the Radium Institute of Paris—a strain which regularly develops 72 per cent of mammary cancer in females but none in males. Bagg produced a high incidence of mammary cancer in mice by rapid breeding and removal of the litter to prevent suckling. These experiments were undertaken primarily to test the theory of stasis in breast ducts as a cause of cancer, and their results seemed to favor that theory. It appears likely, however, that a hormonal stimulation through excessive ovarian secretion may have played a large and perhaps dominant role in the results. Lacassagne has reported the presence of estrogenic substance in human colostrum and in cyst fluid from the breast of a woman with mammary cancer.

Bagg, following the lead of Michalowsky,¹² injected zinc chloride into the testes of fowls and succeeded in causing the development of teratomas during the mating season. By treating these fowls also with injections of anterior pituitary-like substance, he has been able to obtain teratomas at other seasons. There is thus demonstrated experimentally the combined influence of hormonal stimulation and chemical irritation.

The presence of the follicle stimulating factor in the urine is found to accompany teratoma of the testis in man with remarkable constancy. Quantitative measurements of this hormone may even be used to predict which of five different histologic types of teratoma is present in a case that has not been influenced by treatment.

The hormone of the middle lobe of the pituitary, termed intermedin, has been shown to be associated in some way with melanoma.

Parathyroid adenomas have been found associated with osteitis fibrosa cystica, on the basis of which giant cell tumors of the bones frequently develop.

MISCELLANEOUS DATA

I shall now briefly survey some of the miscellaneous data regarding cancer of various organs.

In the skin, numerous types of abnormalities may be precancerous: pigmented moles, oily or dry skin, sebaceous cysts, scars of lupus or burns, and various chronic ulcers.

In the mouth, avoidance of syphilis, tobacco and jagged teeth would largely prevent intra-oral cancer. Betel nut or buyo cheek cancer of the orient may be attributed to a combination of lime, cheap tobacco and irritation caused by particles of the betel nut and the essential oils of the buyo leaves. Electrochemical processes between dissimilar metallic dentures may be a factor in the causation of some intra-oral cancers.

In the esophagus, spasm, excessive heat of ingesta, or irritation by poorly masticated boluses of food, leading to spasm and esophagitis, or scars of peptic ulcers or caustic burns may lead to cancer.

Investigation that I made of the histories of cases of cancer of the stomach and esophagus by a very detailed inquiry into seventeen different postulated factors brought out an interesting discrepancy between the two diseases.¹³ For cancer of the esophagus the factors attaining the higher scores were in the following order: tobacco, alcohol, small intake of water, poor condition of the teeth and lack of teeth. For cancer of the stomach the factors with the higher scores were poor teeth, lack of teeth, other gastro-intestinal diseases, heat of food and drink, irregularity of meals, lack of water, seasonings, use of cathartics, rapid eating, tobacco and alcohol. It may be noted, for example, that for cancer of the esophagus the abuse of tobacco and alcohol took first rank, while in the cases of gastric carcinoma these two factors took much less prominent places. The number of cases studied was too small to permit placing full reliance on such a discrepancy. The main value of the study lies in the demonstration of a clinical method of investigation of the etiology of cancer, a method not appealing perhaps to the experimentalist or to the enthusiast imbued with the notion of finding a universal cause or cure. There is still too little known about the exact clinical settings under which cancer arises in different organs.

In the large intestine, certain cancers are known to arise on the basis of adenomatosis, polyposis or ulcerative colitis. The colon is said to be the most common site of multiple malignant tumors. Ewing observes that "man is the only animal which enjoys unlimited access to food and suffers from restricted opportunity to empty the bowel, and he is the only animal that suffers notably from gastric and rectal cancer."

Cancer of the lung, apparently actually on the increase, mainly in industrial centers,¹⁴ has been attributed to a change in the quality of atmospheric dusts, now laden with combustion products of gasoline and particles from tarred roads. Campbell¹⁵ showed that mice inhaling dust from tarred roads developed an incidence of adenomas of the lungs ten times as great as the controls. Both radium emanations and arsenic are suspected of causing miners' cancer of the lung in Schneeberg and Joachimstal. The effects of respiratory infections, chronic bronchitis and bronchiectasis, and perhaps the influenza pandemic are possible factors in many cases of pulmonary carcinoma.

Aside from the cases in aniline workers the causes of cancer of the bladder are obscure. The American Urological Association's survey of 902 cases showed a low incidence of calculi but a high incidence of multiple tumors (29.2 per cent). This finding, coupled with the observation that has been made in workers in the aniline industry, namely, that there is a high incidence of subepithelial varices and that tumors begin frequently in the basal layers of the epithelium, suggests that carcinogenic agents circulating in the blood may be responsible for some tumors of the bladder.

Carcinoma of the penis is largely the result of chronic irritation due to uncleanness, redundant prepuce and

retention of smegma. It is almost unknown in the circumcised. Teratoma of the testis shows a remarkably higher incidence in undescended testes. Dean¹⁶ estimates that the chances of an undescended testicle becoming teratomatous are from 47 to 273 times as great as those of a normal testis.

Carcinoma of the cervix uteri is notably infrequent in Jewish women, although in general it is commonly believed that birth injuries leading to lacerations, erosions and chronic cervicitis are largely to blame, since it is so regularly a disease of multiparas. Healy,¹⁷ however, has stated that he is quite certain that there is an increasing number of cases in women under 35, many of whom have never conceived. Smith obtained a history of use of saponated solution of cresol douches in a large proportion of women with cervical cancer. An observation common to gynecologists is that cancer of the cervix is very rare in a completely prolapsed uterus, yet in such instances the exposed cervix is certainly subjected to repeated trauma and chronic irritation.

Carcinoma of the body of the uterus is found in single women four times as frequently as carcinoma of the cervix. It occurs mainly beyond the menopause. Carcinoma of the vulva is regularly found to have a basis of chronic changes in the epithelium of the vulva, such as leukoplakia, atrophy and fissuring.

In cancer of the breast, clinical observation shows a high proportion of histories of previous abnormalities of function, such as caked breast, abscess, sore nipples, interrupted nursing, miscarriages or complete lack of use of the breast. It is not at all infrequent in the clinic to note that a cancer of the breast is located in an area of mastitis peripheral to an old scar of incision for breast abscess. Such observations support the theory of irritation of breast and duct epithelium by retained secretions containing butyric and lactic acids and possibly more specific carcinogenic substances. Adair's¹⁸ study of 200 women with mammary cancer showed a normal nursing history in only 8.5 per cent, while in 100 women without breast cancer 80 per cent gave a normal nursing history.

Cancer of the thyroid is known to begin practically exclusively in a diseased thyroid gland.

When osteogenic sarcoma occurs in patients over 50 years of age, in at least 28 per cent it is on a basis of Paget's disease.¹⁹ It is questionable whether trauma may lead to the development of some of the bone-forming sarcomas. It seems likely in some cases that early disturbances, as by rickets, may play a part.

The lymphomatous processes cover a wide range of diseases, some of which, such as lymphosarcoma, are undoubtedly in general malignant tumors, others, such as Hodgkin's disease, are at present subject to dispute as to whether they should be classed with the neoplasms or with inflammatory diseases, and still others, such as acute leukemias, are considered by many to be atypical responses to infection. For most of the varieties of lymphoma one who has access to large numbers of cases could construct a spectrum passing from inflammatory conditions, by insensible gradations, through the typical processes and, beyond, to the highly malignant end of

the scale. With such a variety, no doubt multiple causes are at work. Tuberculosis appears to have some definite but at present indefinable relation to Hodgkin's disease. Steiner,²⁰ using the Seibert tuberculin protein, finds in Hodgkin's disease a marked absence of sensitization to both avian and human tuberculin and explains this finding as indicating either that in Hodgkin's disease there occurs a desensitization to tuberculin or that Hodgkin's disease usually appears in persons in whom a normal reaction to tuberculin does not develop. He suggests that this finding may indicate some obscure relation between the two diseases. However, Uddströmer,²¹ in a recent survey of the occurrence of Hodgkin's disease in Sweden from 1915 to 1931, states that he finds no support for the belief in an etiologic connection with tuberculosis. The reports of numerous investigations on the results of injections of material from Hodgkin's nodes into animals give conflicting evidence on the question of the etiologic relationship to tuberculosis. In the clinic it is difficult to avoid the feeling that Hodgkin's disease may arise on the basis of an atypical tuberculosis. Cases in which the two diseases coexist are by no means rare, and cases are seen not infrequently in which neither the clinician studying the patient nor the pathologist, looking at representative tissue specimens, can decide whether the disease is tuberculosis or Hodgkin's disease.

Lymphosarcoma and chronic lymphatic leukemia appear also to have some relation to tuberculosis. That the causative agent of these diseases in a large proportion of cases probably gains entrance to the body through the gastro-intestinal tract is indicated by increasing recognition of the frequency with which these diseases arise intra-abdominally. Büngeler²² administered small doses of indole to mice over long periods and reported the subsequent development of leukemia, aleukemic myeloses, lymphadenoses and lymphosarcoma. Bernard²³ injected small amounts of tar into the femoral marrow of young white rats and reported the development of erythroleukemia.

It is impossible within the space allotted to do more than indicate briefly some of the widely varying causes of cancers. It seems impossible that such a multiplicity of inciting factors can ever be brought together and found to be operative only in conjunction with some universal growth stimulating substance. While attention has been focused on care of the cancer patient and on animal experimentation, the promising field of detailed clinical investigation of the etiologic factors of the major forms of cancer has been largely passed by. Thus, while many miscellaneous data are at hand, there remains a great need for expansion of our knowledge of the exact conditions under which malignant tumors appear. The opportunity for such investigations will increase as the study and treatment of cancer becomes recognized as a specialty and as more cases are concentrated in special cancer hospitals and tumor clinics.

RELATION OF LEUKEMIA OF ANIMALS TO LEUKEMIA OF MAN

JACOB FURTH, M.D.
HENRY W. FERRIS, M.D.
AND
PAUL REZNIKOFF, M.D.
NEW YORK

Many of the recent contributions to the knowledge of leukemia and related diseases have come through experimental studies in animals. This report is a review of some of these contributions and an attempt to correlate them with the human disease.

LEUKEMIA OF MICE AS A NEOPLASTIC DISEASE¹

Leukemia of a mammal (guinea-pig) was first transmitted by Snyders, but most of the experimental studies that established the neoplastic nature of this disease were made with the leukemias of mice.

Leukemia of mice, both lymphoid² and myeloid,³ is transmissible to healthy individuals of the same species. Transmission is successful only with live leukemic blood cells, and the inoculum loses its ability to transmit the disease when subjected to such procedures as glycerination and desiccation in the frozen state, which injure live cells while they do not destroy viruses and microorganisms. Cell-free extracts fail to transmit the disease.

The source of the leukemic blood cells does not appear to influence transmissibility, and transmission is readily accomplished with a suspension of apparently any organ infiltrated by the immature cells. Leukemic blood cells readily transmit the disease, but cell free plasma does not.

Carcinoma and sarcoma of mice can likewise be passed from one animal to another only by means of live tumor cells. The transfer of leukemia is essentially a graft of immature blood cells from leukemic to healthy mice. The blood forming organs of the recipient play no active part in the development of leukemia following the inoculation. Indeed, the disease may be transmitted to mice whose normal blood forming organs have been destroyed by massive doses of x-rays preceding the inoculation. Mice thus treated may die before the normal blood forming organs injured by the x-rays undergo regeneration. The duration of the disease in irradiated mice is the same or somewhat shorter than in mice not irradiated. Potter and Richter⁴ traced the lymphocytes that infiltrated the various organs to those introduced, by means of microscopic studies, at various intervals after subcutaneous inoculation.

Transmission of some strains of leukemia is successful only in closely related mice, others may also be transmitted to unrelated mice. The factors that deter

mine the success of inoculation are similar to those that determine the fate of a tumor transplant

The disease produced by intravenous inoculation has the character of the systemic disease leukemia and is indistinguishable from the spontaneous disease. After subcutaneous injections the immature blood cells form, with rare exceptions, tumors at the site of introduction.

The type of disease produced depends on numerous factors, of which the character of the malignant blood cells is most important. Each of nine strains of lymphatic leukemia studied in our laboratories showed individual characteristics that were retained through numerous animal passages, with only slight modifications such as occur among other transmissible neoplasms.

Morphologically the strains of lymphatic leukemia studied differ as to the size, shape, basophilia of the malignant lymphocytes, presence or absence of azure granules and of vacuoles, and fragility as revealed by the presence of smudged (crushed) cells in dry smears prepared in a uniform manner. The malignant cells of the two strains of transmissible myeloid leukemia observed differ with respect to the size of the cells and to the number and size of the granules they contain. Individual cells of different strains cannot always be differentiated from one another morphologically, but groups of cells derived from different strains can usually be distinguished.

Far more numerous are the differences among the transmissible strains of leukemia, revealed in transmission experiments, such as localization and intensity of infiltrations, ability to produce tumors, and the ease of transmissibility to related and unrelated mice.⁵

It is evident from these studies that the leukemic blood cells of mice are not common immature blood cells, they are malignant cells with characteristics of their own.

Several agents that may produce leukemia in mice have been described, such as indole (Bungeler⁶), benzene (Lignac⁶), and x-rays (Krebs, Wagner and Rask-Nielsen⁷ and Furth⁶). Krebs and his associates observed leukemia six times more often among mice that were irradiated than among their unirradiated controls. It is noteworthy that these studies on the production of leukemia by x-rays and benzene have followed observations on human beings suggesting the causation of some cases of leukemia by these agents. In our laboratories mice have been irradiated by massive doses of x-rays at the age of from 2 to 3 months. From six to eighteen months later many of them developed one of three types of neoplasm: (a) mediastinal lymphosarcoma with or without generalized lymphomatosis, (b) myeloid leukemia and (c) ovarian tumors. The incidence of these diseases was approximately ten times greater among irradiated mice than among their unirradiated siblings. Two cases of myeloid leukemia occurring in irradiated mice proved to be transmissible.⁷ The transmitted disease was indistinguishable from the spontaneous.

The inference can be drawn from these observations that leukemia like cancer can be produced by chemical or physical agents, leukemia produced by x-rays can be transmitted from diseased to healthy animals.

The strains of transmissible leukemia studied have a period of latency of from three weeks to three

months, during which the animals appear healthy, while the malignant blood cells introduced by the intravenous route multiply in the blood-forming organs. Victor⁸ found very recently that this period of latency also exists in the spontaneous disease, demonstrable by changes in the respiratory metabolism of lymph nodes and by transmission experiments made with lymph nodes removed from mice during this period.

In summary, variations in the course and anatomic manifestations of leukemia of mice are determined by several factors. Some are intrinsic and are determined by the constitution of the host and of the malignant blood cells. Others are extrinsic such as the site of

Fig. 1.—Lymphoid leukemia, lymphocytes in the circulating blood. A and C are from mice. B is from child J. P.

origin or entry of the malignant cells, the possibility of their free discharge into the circulation, and the numerous factors that influence the resistance of the host.

THE SIMILARITY OF LEUKEMIA OF MAN TO THAT OF THE MOUSE

Experimental studies indicate that leukemia of mice is a neoplastic disease. How closely does leukemia of man resemble the disease of the mouse, and is one justified in considering it also as neoplastic in nature?

The anatomic manifestations of the various types of leukemia in mice resemble so closely those in man that no essential difference has been found between the two by workers familiar with both. Despite this evidence,

⁸ Victor, J. Personal communication to the authors.

however, some observers familiar with the human disease are skeptical as to a similarity. It has therefore appeared worth while to make a detailed comparative study of the leukemias and related conditions in these two species. For this purpose we have studied twenty-five cases of leukemia (ten lymphoid and fifteen myeloid), ten cases of lymphosarcoma and three cases of myeloma which came to postmortem examination. The material of mouse leukemia has come from the experiments performed in our laboratories.

In all instances of myeloid leukemia of both man and mice studied by us, the normal bone marrow is extensively infiltrated by immature myeloid cells which show disturbed or arrested maturation to normal polymorpho-

The same observations apply to lymphoid leukemia. Enlargement of lymph nodes almost invariably occurs in lymphoid leukemia of both species. The extension of infiltrations beyond the capsule occasionally found in this disease (fig 6) induced many pathologists to regard lymphoid leukemia as a neoplastic disease. Lymphoid leukemia may occur with or without tumor formation, and there are transitional forms between lymphosarcoma and lymphoid leukemia in both species. Lymphosarcoma terminating in lymphoid leukemia (so-called leukosarcoma) is known to occur in both man and the mouse.

Figures 1 to 7 illustrate the similarity of the changes in various organs in the leukemias of man and the mouse. Indeed it is often difficult, if possible at all, to tell from which species the photomicrographs were prepared.

Evidence of inflammation or degeneration is either secondary or absent. Leukemia occurs in small numbers of individuals in any population of mice or human beings and does not spread from affected to healthy individuals although it is fatal in both species.

Any type of cell that is capable of multiplication may, from the theoretical standpoint, produce a neoplasm and immature blood cells should be no exception. The fact that leukemic cells circulate in the blood stream is not opposed to the concept that they are neoplastic in nature, since they may be found in the tissues in large numbers, often forming discrete nodules. Moreover in animals leukemic cells from the blood may form distinct tumors when placed in the subcutaneous tissue.

Ewing⁹ quotes several definitions of neoplasia applicable to the leukemias of mice. In view of the close similarity between mouse leukemia and that of man, is it not logical to consider the human disease as also neoplastic?

THE RELATION OF ACUTE TO CHRONIC LEUKEMIA

It is now generally accepted that the human disease is the result of an overgrowth of immature blood cells in the blood forming tissues, with secondary invasion of the circulating blood. It is believed by some that this overgrowth of immature blood cells may result from an acute infection¹⁰ and progress rapidly; therefore, the disease is called acute. Chronic leukemia, notably the lymphoid, is regarded by most workers as probably neoplastic in nature.

Experimental studies of the animal diseases have shown that there is no essential difference between acute and chronic leukemia. The first generations of the disease produced by transmission often have a chronic course of from one to three months. During repeated passages the virulence of most strains increases so that the experimental disease may terminate fatally within a week. Lymph node and splenic enlargements are usually considerable in the chronic disease but slight in the acute variety. Some transmissible strains remain chronic, others follow a rapid course after isolation and are often associated with extensive hemorrhages and sudden prostration, suggesting an acute infection. Nevertheless, in transmission experiments, both the acute and the chronic cases behave like neoplasms, the anatomic changes are essentially the same in the two transmission being dependent on the presence of live immature blood cells in the inoculum.

Fig 2—A, extensive infiltrations in the kidney in lymphoid leukemia of man; B, same in the mouse.

nuclear leukocytes. Through the bony canal system the immature blood cells may spread to the periosteum and surrounding tissue in both man and the mouse. The pulp of the spleen becomes densely packed with similar cells in the two species. The involvement of lymph nodes occurs less often and is less conspicuous in myeloid than in lymphoid leukemias, whether of man or of mouse. The infiltrations in the liver are either portal or diffuse (fig 3) or both. Small tumors composed of immature myeloid cells may occur in both man and the mouse in numerous locations, e. g., skin, bones and liver. The type of cell that forms infiltrations or tumors in the various organs is usually the same in the same case but may be different in different cases, whether in the mouse or in man. Mitotic figures are occasionally seen among the immature blood cells.

¹⁰ Ordway, Thomas, Gorham, L. W., and Beebe, R. T. *Oxford Medicine*, New York: Oxford University Press, 2: 683, part 2, 1933.

A postmortem study of the human cases likewise fails to reveal criteria by means of which the disease could be divided in two different varieties, namely, acute and chronic. This classification, accepted by many textbooks of pathology and medicine, found its origin in clinical studies but is not substantiated by anatomic studies of our material. In the cases of clinically acute

There is some indication in most clinical histories obtained from patients with acute leukemia that the disease had been in progress long before the onset of the infection that led to the diagnosis. Manifestations of illness such as fatigue, pallor, lassitude, anorexia (in children), epigastric discomfort, dependent edema, purpura and similar symptoms are often present but are not mentioned by the patient until he has been carefully questioned.

Twenty-four patients with acute or subacute leukemia (seven lymphoid and seventeen myeloid) were studied for the relationship between the apparent onset

TABLE 1—Duration of Symptoms in Eighteen Cases of Acute or Subacute Leukemia

| Duration of Symptoms | Judged by Patient Cases | Judged by Careful History Cases |
|----------------------|-------------------------|---------------------------------|
| 2 weeks or less | 4 | 0 |
| 2 weeks to 1 month | 5 | 1 |
| 1 month to 2 months | 4 | 1 |
| 2 months to 4 months | 1 | 3 |
| 4 months to 6 months | 2 | 2 |
| 6 months to 1 year | 2 | 3 |
| 1 year to 2 years | 0 | 5 |
| More than 2 years | 0 | 3 |

leukemia that came to postmortem examination the changes in the bone marrow were similar to those of chronic leukemia. The infiltrations in other organs were slight or moderate in a few cases of clinically acute disease, but in the majority of cases they were as conspicuous as in the chronic disease. In one case studied through the courtesy of Dr. Jacob Werne, there was a fulminating necrotizing infection of the pharynx and larynx which caused death after an illness of

TABLE 2—The Range of Temperature in Leukemia

| | Number of Cases | |
|---------------|-----------------|---------|
| | Acute | Chronic |
| Normal | 8 | 8 |
| 37.5 to 38° C | 9 | 7 |
| 38 to 39° C | 5 | 11 |
| Above 39° C | 7 | 8 |

apparently one week's duration, but the postmortem examination revealed extensive leukemic infiltration in the bone marrow, spleen and lymph nodes. Interference with normal leukocyte formation may explain the poor resistance to infection. Stasis of immature blood cells in the capillaries, interference with megakaryocyte formation and the low platelet count may explain the hemorrhagic diathesis¹¹ which is often associated with leukemia.

TABLE 3—Frequency of Infection of the Upper Respiratory Tract*

| | Acute Leukemia | Chronic Leukemia |
|--|----------------|------------------|
| Number of cases with evidence of inflammation | 9 | 10 |
| Number of cases with no evidence of inflammation | 15 | 18 |

* The analysis of clinical symptoms and signs (tables 1-3) includes also cases that were not examined post mortem.

Experimental leukemia both acute and chronic, is preceded by a period of latency, dating from the time of inoculation until the onset of symptoms, during which the animal appears healthy. The sudden termination of the disease, although it may resemble or be associated with an infection, occurs in mice whose blood-forming tissues, usually bone marrow, have been largely replaced by the malignant blood cells during the period of latency.

Fig. 3—A, diffuse infiltration of the liver in myeloid leukemia of man; B, same in the mouse.

of symptoms as judged by the patient and the probable beginning of the disease as determined by a careful history. In six of the twenty-four cases an adequate history could not be elicited. The results of the study in the other eighteen cases are given in table 1.

Table 1 shows that symptoms of illness are present in most cases of acute leukemia before the onset of the infection from which the beginning of the disease is often dated. It is evident from experimental studies that, at the very beginning, leukemia is not associated with symptoms of illness.

Fever frequently occurs in leukemia, but it is also found in many conditions other than infections, e.g., in the anemias. Moreover, it occurs in both acute and chronic leukemia (table 2).

¹¹ Hamburger, Werner. Beitrag zu den Gehirnveränderungen bei Leukämie (besonders über die Frage der Genese der Blutungen). Frankf. Ztschr. f. Path. 40: 257, 1933.

Infection of the upper respiratory tract is often found in acute leukemia but it also occurs in chronic leukemia (table 3)

These data indicate that leukemia is often terminated by an infection but there is no evidence that it is caused by it. Evidently an individual whose normal blood forming tissues are replaced by pathologic blood

Fig 4—A portal infiltration of the liver in lymphoid leukemia of the mouse B same in man

cells cannot combat an infection as readily as a normal individual

From clinical and pathologic studies of fourteen cases of acute leukemia of children, Gittins¹² recently arrived at conclusions similar to ours. Concerning the differentiation of changes in the bone marrow in leukemia and in infection the reader is referred to his article

TUMOR FORMATION BY IMMATURE BLOOD CELLS (LYMPHOSARCOMA, MYELOMA)

Morphologic studies in man and experimental studies in mice indicate that lymphosarcoma and lymphoid leukemia are related diseases

In experimental lymphoid leukemia of mice the malignant blood cells of some strains, when introduced in the subcutaneous tissue, form huge tumors invading adjacent structures by continuity but do not invade the blood stream. Malignant lymphocytes of other strains, on the contrary, form slight or no tumors in the injected subcutaneous tissue but readily invade the blood, producing the blood picture of leukemia

Similar differences were found between two strains of transmissible myelosis studied. These properties of the various transmissible strains of lymphomatosis and myelosis are retained through numerous successive animal passages and are not permanently modified by the host, hence they are due to inheritable (genetic) differences among the malignant blood cells of the different strains. These properties can be demonstrated also by intravenous inoculation by means of which malignant lymphocytes of some strains produce lymphoid leukemia, others a similar disease with slight or no blood involvement

Generally speaking, malignant blood cells that have the ability to produce leukemia with high blood counts form small or no tumors in the injected subcutaneous tissue, whereas malignant blood cells that produce the aleukemic disease usually form large tumors. Tumors

may also develop after intravenous inoculation, notably with lymphocytes that have little or no ability to invade the blood

In a very recent study on the histogenesis of lymphosarcoma, Ehrlich and Gerber,¹³ discussing the applicability of our studies in the mouse to the human disease, state that "the manner in which a 'virus' reaches a lymph node does not explain why once involved, the process is invasive and destructive in one case (lymphosarcomatosis) and hyperplastic in the other (lymphadenosis)." On the contrary, in our paper² cited by these workers we have demonstrated (a) that mouse leukemia is not caused by a virus and (b) that it is a neoplastic and not a hyperplastic disease, (c) the type of disease is determined by several factors. The character of the malignant lymphocytes and the route of entry are sufficient to explain most if not all the differences between lymphosarcoma and lymphoid leukemia

Another factor that determines whether a mouse will develop the systemic disease or tumors following intravenous inoculation was revealed in the study of transmissible myeloid leukemia of strain Ar117. The immature malignant myeloid cells of this strain produce slowly growing single or multiple myeloid tumors (myeloma) in resistant mice, and myeloid leukemia with no tumors in mice whose susceptibility is decreased by irradiation with x-rays shortly before inoculation.

The differences found in the results of intravenous and subcutaneous inoculations indicate that the type of spontaneous disease is also influenced by the site of origin of the malignant blood cells and the possibility of their free entrance into the circulation

The observations made in the study of the human disease are in harmony with the experimental studies in mouse leukemia. The lymphosarcoma cells have the ability to invade adjacent structures, but blood invasion in human lymphosarcoma occurs, as has been recognized by Ghon and Roman.¹⁴ The study of our human material suggests that blood invasion is far more

Fig 5—A leukemic (neoplastic) hyperplasia of the bone marrow in lymphoid leukemia of man B same in the mouse.

common than is generally supposed. Invasion of the circulation by lymphosarcoma cells is suggested by microscopic changes such as infiltration in the portal tissue throughout the liver, diffuse infiltration of the spleen, and leukostasis (fig 8 A)

¹³ Ehrlich J. C. and Gerber I. E. The Histogenesis of Lymphosarcomatosis. *Am J Cancer* 24 1 (May) 1935
¹⁴ Ghon A. and Roman B. Ueber das Lymphosarkom. *Frankfurt. Ztschr f Path* 19:1 1916

¹² Gittins R. Leukemia (Leukosis) in Children. *Arch Dis Child* 8: 291 (Oct) 1933

Locally invasive growth, a feature of myeloma or lymphosarcoma, was conspicuous in six and very slight in seven of fifteen cases of human myeloid leukemia. It was conspicuous in four and very slight in four of ten cases of lymphoid leukemia. There was evidence of hematogenous spread in four of ten cases of lymphosarcoma. However, the small number of sections

Fig 6—A lymph node with episcapsular infiltrations in lymphoid leukemia of the mouse. B same in man.

available for microscopic study allows no conclusion regarding the frequency of these changes.

Two cases of so-called reticulum-cell sarcoma have not been included in this study. Their relation to the leukemias is obscure, as is their histogenesis.

The problem of myeloma has recently been reviewed in an editorial in *THE JOURNAL*.¹⁵ Our series includes three cases typical of the so-called plasma-cell myeloma. In one, the tumors were localized to the bones, in the other two they were associated with infiltration or tumors of internal organs as seen in lymphomatosis. Morphologically the cells composing these tumors resemble as closely erythroblasts as the plasma cells of Marshall.

Myeloid tumors composed of myelocytes and myeloblasts, some terminating in myeloid leukemia are well known in the literature.¹⁶ One of the two transmissible strains of myeloid leukemia studied by us produces single or multiple myeloid tumors about the bones, the other does not, but both produce myeloid tumors in the injected subcutaneous tissue.

OBSERVATIONS ON THE PATHOGENESIS

Experimental studies indicate that leukemia results when normal white blood cells assume the characteristics of malignant cells. The various manifestations of this disease may be explained by the characteristics of the malignant blood cells, the site of their origin, the possibility of their free entrance into the circulation and the resistance of the host.

Malignant blood cells entering the circulation are at first retained in numerous organs (e.g., bone marrow, spleen, lymph nodes) and multiply at sites favorable for their growth. Hence the gradual enlargement of lymph nodes in most cases of lymphoid leukemia and the infiltration of the bone marrow. This is the first stage of the disease and may be unnoticed. It is followed by invasion of the blood with immature cells in great quantities. These cells may be retained in the

capillary bed of numerous organs (leukostasis), for example, liver and kidney, seldom in the skin, or they may form extravascular infiltrations.

Leukostasis is a common and characteristic finding in leukemia and comparatively little attention is given it. It occurs not only in cases with high leukocyte counts but also in the so-called leukopenic variety (fig 8B) of the disease and may be occasionally found in lymphosarcoma (fig 8A). We know of no disease in which a selective retention of large numbers of very immature blood cells occurs in the capillary bed, other than leukemia, either of mouse or of man.

Leukostasis is usually conspicuous about sites of hemorrhage. The massing of immature leukocytes in blood vessels is sufficient to explain hemorrhage, which often occurs in the presence of a normal thrombocyte count and clotting time.¹¹ Figure 8B shows leukostasis in a child with lymphoid leukemia, whose leukocyte count at the time of death was 1,000, as the result of massive irradiation with x-rays.

There are several recent publications stating that leukemic blood cells are formed from endothelial or reticular cells of organs such as the liver and the spleen.¹⁷ Jaffe¹⁸ states that even resting fibrocytes may display blood-forming potentialities and that the leukemic process is characterized by the hematopoietic activity of the entire mesenchyme.

In leukemia there is frequently extensive proliferation of histiocytes in lymph nodes, spleen and liver. The possible relation of reticulum cells to lymphosarcoma is suggested in some cases of lymphosarcoma but in none of the cases of human leukemia studied by us is there any evidence of blood formation by histiocytes or by endothelial or reticular cells.

Fig 7—A lymphocytes producing leukemic infiltrations in the mouse shown at higher magnification. B same in man.

Studies on the nature of the histiocytes (Kupffer cells) of the liver have recently been made by Dunning in association with one of us.¹⁹ In sections of liver stained by Horte's

silver carbonate method for microglia the histiocytes exist as independent elements scattered diffusely throughout the organ. They lie in and about the sinusoids between the liver cells which entirely surround them and in the perivascular connective tissue. In cultures of liver of chicken and guinea pig embryos, the histiocytes maintain their individuality and their independence from other cells and exhibit no erythropoietic or leukopoietic ability.

Morphologic studies are difficult of interpretation and often do not permit definite conclusions. In the controversy as to whether in leukemia the infiltrations of the various organs are the result of metaplasia or colonization (metastasis) strong support is given the latter view by experimental studies. The immature blood cells in the circulation and organs of inoculated mice have the characteristics of those introduced. It is very improbable that the host would produce cells with precisely the same individual characteristics. This is especially unlikely in experiments in which the mice have been so heavily irradiated preceding the inoculation that their ability to produce normal blood cells is almost lost. Yet the course of the disease in these animals is

Fig. 8—A leukostasis in the kidney in lymphosarcoma of man. B leukostasis in lymphatic leukemia of man after x-rays reduced the number of circulating leukocytes to 1 000 per cubic millimeter.

the same as in mice not irradiated, and similar to that of the mouse with the spontaneous disease from which the malignant cells are derived.

Naegeli²⁰ called attention to a fundamental difference between the blood picture in simple hyperplasia of the bone marrow and in leukemia. In the former there are continuous transitional forms between the mature and the immature granular leukocytes, a "shift to the left" in Arne's terminology. In leukemia there is a proliferation of primitive blood cells with diminished or with no maturation to polymorphonuclear leukocytes, often there is a hiatus between the mature and the immature forms, called by Naegeli "leukemic hiatus." Microscopic studies of organs more readily demonstrate this hiatus than do blood smears. The inflammatory cells of the exudate in the alveoli of the lung occurring in pneumonia associated with several of our cases of leukemia were polymorphonuclear leukocytes, the leukemic cells that accumulated in the capillaries (leukostasis) were immature myeloid cells without transitional forms between the two. In the

blood and blood forming organs many types of white blood cells may be present, but the leukemic infiltrations outside these organs are composed almost invariably of the malignant cells only.

CONCLUSIONS

Leukemia of man is essentially the same disease as leukemia of mice. Both the acute and the chronic forms lymphoid as well as myeloid, are neoplastic diseases. The immature blood cells in leukemia are malignant cells, which may form tumors or diffuse infiltrations and possess characteristics of their own. Studies of leukemia of the mouse indicate that leukemia, like cancer, is of multiple etiology, its development and manifestations are dependent on intrinsic (genetic) and extrinsic factors. An analysis of these factors in the mouse and their role in the human disease requires further study.

1300 York Avenue

ABSTRACT OF DISCUSSION

ON PAPERS OF DR. CHAMBERLAIN, DR. CRAVER AND
DRS. FURTH, FERRIS AND REZNIKOFF

DR. G. E. RICHARDS, Toronto. For twenty years those who have been engaged in roentgen and radium therapy have been wrestling with the problem of dosage and have gone through the periods when dosage was looked on as purely a physical matter. Dr. Chamberlain has made it clear that, in the presence of the perfected apparatus, dosage is a biologic matter. The correct dose is the dose that best suits the needs of the individual patient at a given time and presupposes the use of a standardized preparation. No dose of x-rays can be a pre-determined, mathematical calculated dose. It must be a dose administered and controlled by the observed tissue reactions in the individual. These observed tissue reactions are of as much importance to radiologic physicians as blood sugar estimations are to the physicians engaged in the treatment of diabetes. The unknown will always be the individual response and this must be controlled regardless of any dose, no matter what it may appear to be on paper. The problem of dosage is as nearly solved as many of the problems of drug therapy. There is available a highly efficient form of therapy, almost an instrument of precision and the application of this instrument to the problems of disease, particularly the problem of cancer, remains an individual one that can never be reduced to a standard formula. Dr. Chamberlain has spoken of the possibilities along the line of super high voltage therapy. It has always seemed to me that the answer to this question was provided by experience with large units of radium from 4 to 8 Gm. as these represent a wavelength of the order of one million volts or one and one-half million volts and the answer to that question can be obtained from the study of this particular work quite as well as and probably more quickly and accurately than from x-ray machines or x-ray tubes operating at a million volts.

DR. T. R. WAUGH, Montreal. From the standpoint of the hematologist the experimental production of leukemia in animals offers a most important method of approach to the problems associated with these conditions. On the other hand from the standpoint of the pathologist I think that one should be a little hesitant about accepting as established the neoplastic nature of these conditions. It is hardly justifiable to define the leukemic process as identical with neoplastic growth, when as a matter of fact the absolute criteria of tumor growth are as yet by no means certain. In the second place there is undoubtedly in the various forms of leukemia in man a wide range which approaches the hyperplasias on the one hand hence called hyperplastoid, and the tumors on the other hence referred to as sarcomatoid. This fact has led to the introduction in the scale of proliferative activities between hyperplasia and neoplasia and merging into them on either side of a third type designated as cataplasia and the leukemias fall into this division. Cataplasias have neither the complete differentiation of cells and preservation of functional activity, which charac-

²⁰ Naegeli, Otto. *Blutkrankheiten und Blutdiagnostik*, ed. 5. Berlin: Julius Springer, 1931.

terizes the hyperplasias, nor the independent atypical manner of growth of the neoplasias. Nor is the introduction of this intermediate type merely a name, for it represents a biologic principle and law of growth. One finds the same stages in development of malignant tumors as in cancer of the breast, in which one can trace the transition of proliferative activity of epithelial cells from a simple hyperplasia through a stage of abnormal development and immaturity to true neoplasms. As regards cancer, Dr Craver has pointed out the need of an investigation of the predisposing factors as encountered in the patient, and this is undoubtedly an important field, particularly open to the clinician. For the research workers there appear to be three main methods of approach. There are first those who study the cancer cells themselves and see in them specific attributes, they might be called specificists. Secondly there are those who investigate the stimulating and irritating factors, they might be termed etiologists. Finally there are the comparatively few who look to the changes within the host which allow the malignant growth to take place, they see in the environment of the proliferating cells the real secret of their emancipation and might be termed environmentalists. Cancer might be likened to a runaway horse. Witnessing such an event, some would be interested in the horse itself, others would wonder what frightened the horse while a few would be concerned with why the horse got away and could not be controlled. Horses frequently get frightened but seldom run away. I am inclined to believe that too much attention has been paid to the various stimulating agents and the cancer cells themselves, to the neglect of that other, most important factor, the host.

DR. L. K. DIAMOND, Boston. The difficulties of determining the etiology of cancer in general and leukemia in particular become greater when the disease occurs in the infant and child rather than in the adult. Leukemia is so much more likely to be an acute fulminating process in the young with symptoms and signs frequently similar to those produced by an infectious process, that even after years of study the evidence for the neoplastic nature of the disturbance has been scant. Too often leukemia in childhood is associated with hyperpyrexia, pain in various organs, the presence of extremely immature, difficult-to-recognize leukocytes and a rapid, fatal course. Infection in this age group often is followed by the same group of symptoms. Therefore the best lead to the understanding of the cause of leukemia in such cases is the comparison of the experimental leukemia in animals with that in human beings. Two years ago I started studying the course of leukemia experimentally produced in mice and was impressed by its similarity to that in infants and children. In fact, examination of tissues from each side by side, showed the impossibility of differentiating the two in many cases. An interesting observation was the fact that a malignant cell can be so specific when injected into a susceptible host by a single route as to produce the same group of symptoms and signs, a similar course and identical changes in the various organs involved in every mouse. In a review of seventy-five cases in infancy and childhood seen during the last eight years it became readily apparent that the leukemias could be divided in a fashion different from that used previously. In fact many similar case histories occurred in which the onset of symptoms, the development of signs, the course of the disease, the character of the malignant cell and its level in the blood, the type of termination and the changes in the organs at necropsy were similar in many respects. This was used as a basis for classification. In forty-five cases certain definite groups could be separated. One easily recognized type invariably started with pain in a single joint followed by hyperesthesia, pains in several joints or bones, limitation of motion, irritability, weakness and fever. Rheumatic fever was most commonly suspected. However the development of pallor, petechiae, enlarged liver and spleen and numerous immature forms of leukocytes even though their level in the blood was not high followed by a rapid terminal anemia and death within a few months with necropsy evidence of leukemia was invariably associated with a small, malignant lymphocytic cell. Another group showed gradual development of pallor, weakness, abdominal pain, generalized glandular adenopathy, extreme hyperpyrexia and a rapid termination in

a few weeks, associated with a single type of malignant lymphoid cell. It has been possible to recognize four other types of malignant cells, each of which is associated with a definite and characteristic progression of symptoms, signs, termination and infiltration of organs.

DR. CHARLES C. LUND, Boston. Dr Chamberlain mentioned biopsy. Many people are still afraid of biopsy. They are afraid that the cancer will be spread by the procedure. I believe that a biopsy done properly on a reasonably accessible tumor is almost universally indicated and that it is perfectly harmless if followed, within a few days or preferably a few hours, by adequate roentgen, radium or surgical treatment. Dr Craver listed many of the known factors in the etiology of cancer. I am going to show how some of these factors may work on one another. There will be cases in which, of course, a single factor is important, and that is the only important one. An example might be x-ray cancer. A sufficient dose of x-rays will certainly produce cancer in every subject. The only difference that the changes in the host will make in that situation will be the rapidity with which the cancer will develop. On the other hand, certain people are born with conditions that are sure to terminate in cancer if they reach an advanced age. One of the worst offenders in that line is multiple polyposis of the intestine. There are others. Inheritance and irritation are both important in skin cancer and by that I mean ordinary common basal cell as well as epidermoid skin cancers. For instance, the person with red hair and very light skin is much more irritated by sunburn or other exposure than the Mediterranean type of person, or he, in turn, than the Negro. With the same exposure to the elements, the incidence of skin cancer in the redheaded individual with light skin is probably ten times what it is in the Italian, Greek and Spaniard. Again, their incidence is probably ten times that of the Negro. The type of skin is what is inherited. The irritation, added to susceptibility, is what produces cancer at a given time in a given case.

DR. W. EDWARD CHAMBERLAIN, Philadelphia. I thank Dr Lund for giving his opinion on biopsy. It is a number of years since I thought of the time when physicians were a little afraid of biopsy. It is now being done universally, and many statistics have been accumulated or much experience has been gained to indicate that it is a perfectly safe procedure when properly carried out.

DR. JACOB FURTH, New York. From the theoretical standpoint any type of cell that has the ability to multiply may undergo unrestricted multiplication and produce a neoplasm. Blood cells should be no exception. When cells of a breast gland undergo unrestricted multiplication one expects to find a growth in the breast. What change is expected when cells that exist as detached individuals and that readily find their way into the blood stream and grow particularly well in certain organs, e. g., bone marrow, spleen and lymph nodes, undergo unrestricted multiplication? One would expect to observe precisely the manifestations of disease that are found in leukemia. Immature cells of the bone marrow injected into normal animals disappear from the blood and the animals remain healthy. When a few immature blood cells, less than ten, from an animal with leukemia are injected into a normal animal the cells introduced multiply unrestrictedly with no apparent purpose until the host dies. Studies of human leukemia led to no definite conclusion concerning the nature of this disease, but studies in animals yielded conclusive results. Those who have availed themselves of the opportunity to study leukemia of mice have come to conclusions similar to those presented by us. We hope that Dr Waugh may also avail himself of this material and reach the conclusion that the human disease is neoplastic and its manifestations are similar to those of the animal disease.

Inspection and Palpation—The examination of the cardiac area by inspection and palpation is too often neglected. The accurate diagnosis of cardiac conditions by the average practitioner can be accomplished far more easily and accurately by the use of inspection and palpation than by auscultation.—Dr E. J. G. Beardsley, quoted by Fisher, *Alexander Aphorisms in Clinical Medicine* *Canad J Med & Surg* 77:166 (June) 1935.

LOBAR COLLAPSE IN CHILDREN

GLADYS L. BOYD, M.D., FRCP (C)

TORONTO

The collapse of one lobe of the lung may take place in various locations and from several causes. Its actual occurrence is so restricted to the atelectasis of a lower lobe, characterized radiologically, by a basilar triangular shadow, that its discussion is practically limited to the study of the latter condition. Since Dieulafoy¹ first described these shadows in 1910 there has been no dearth of literature on the subject. My only excuse for adding to its volume is the clinical and pathologic material that I have to present, which may add to the elucidation of a still unsettled problem.

Before proceeding with the discussion of basilar triangular shadows, I would like to mention the rarer

ences from the usual picture of pneumonic consolidation. It was homogeneous. The lower border was sharply defined, and perhaps, most important, the mediastinum was shifted to the diseased side. Post mortem examination revealed an atelectatic bronchiectatic right upper lobe. There was no pigment present, but this was insufficient evidence to warrant the conclusion that the lesion was congenital.

A basilar triangular shadow may be described as a homogeneous opaque shadow in the form of a right angled triangle having for its base the diaphragm, one side the mediastinum, and a hypotenuse formed by a line extending from the hilus to some point on the diaphragm. The latter may be straight, convex, concave or slightly irregular in its outline. Importance is attached to its character as varying with the underlying cause. These opaque areas until quite recently have been attributed to mediastinal pleurisy, seldom

cases in which lobar collapse of an upper lobe occurs. Years ago, Heller² described a series of cases of bronchiectasis in children from 9 months to 7½ years of age. The lesions involved whole lobes, usually upper ones, and were characterized by collapsed lobes with pus-containing cavities separated by narrow septums and containing little lung tissue. He considered them to be congenital in origin. I have noted that acute bronchiectasis in infancy much more frequently involves these lobes than would be expected from the prevalence of lower lobe infections in older children and in adults. During the life of an infant who died at 6 months of age with a history of infections of the respiratory tract for three months, a roentgenogram was considered a picture of chronic bronchopneumonia. Consideration of the roentgenogram showed several important differ-

proved, and to fibrosis of the lung. Savy³ and Wallgren⁴ have both demonstrated purulent effusion. The hypotenuse in these cases is convex. Armand-Dehille, Levy and Marie⁵ in 1925, and shortly afterward Singer and Graham,⁶ were the first to associate this picture with pulmonary collapse. The former observers noted its association with saccular bronchiectasis, while the latter described its occurrence in a radiologic study of bronchiectasis and noted the collapsed condition of such lobes when removed surgically. Rist and his co-workers⁷ recognized its association with bronchiectasis but did not appreciate its pathologic significance. Granting that this shadow occurs most often in bronchiectasis and by some is regarded as pathognomonic, it is well to point out its possible occurrence in other diseases. Mention has already been made of authentic cases due to pleural effusion. Anspach⁸

Read before the Section on Pediatrics at the Eighty-Sixth Annual Session of the American Medical Association Atlantic City N. J. June 12 1935.

From the wards and laboratories of the Hospital for Sick Children and the Department of Pediatrics University of Toronto under the direction of Alan Brown M.D. FRCP (C).

reports a case of congenital heart disease showing this picture. Recently one similar case in a young infant was seen in this clinic. In one other child with rheumatic carditis there was a triangular basilar shadow on the right side which on cursory examination presented the picture of pericardial effusion, but closer study showed its true nature. Iodized poppy-seed oil was injected in this case but revealed no bronchiectasis.

Space will not permit either the display of the roentgenograms of all my cases or their case histories. The accompanying table summarizes the essential points and such roentgenograms are shown as will demonstrate the essential points. Physical signs are not given in the table because there is no constancy in those found, except the cardiac displacement to the diseased side. Sometimes they are such as to suggest the presence of lobar collapse without the aid of a roentgenogram, but they vary considerably. There is usually dullness, more or less marked altered breath sounds and some moisture, but such signs are not sufficiently characteristic to differentiate these from other lesions of the lower lobe.

Pathologic specimens were obtained from four patients either by surgical removal or at autopsy. In all, the lobe was greatly shrunk.

Fig 1 (case 7) —E. V. had bronchiectasis from 1½ years of age. Death occurred at 3½ years as a result of an accident.

The upper lobes were enlarged to fill up the space ordinarily occupied by the diseased lobe. In three of the four the collapsed lobe was the only pathologic basis for the triangular shadow, in the fourth case a shadow might have been produced by the fibrous adhesions that extended from the hilus to the base. The pleural adhesions were not marked and could be separated without tearing the lung tissue. The cut surfaces showed numerous dilated bronchi ending in saccular or cylindric dilatations. These were separated by narrow strips of tissue. The bronchial mucosa was thrown into transverse ridges. The parenchyma was much reduced in amount collapsed and nearly airless. There was some fibrosis in all cases.

Microscopically, almost no normal lung tissue was to be seen. The few remaining alveoli were collapsed and thick walled. There was some pigment in every patient except the baby, who was too young to be expected to have any. The bronchi were widely dilated and lined with stratified columnar epithelium. In some areas the lining was replaced by granulation tissue. There were a few islands of cartilage remaining. Some of the bronchi had cilia and a few had hypertrophied mucous glands. The stroma was invaded by lymphocytes, eosinophils and polymorphonuclear cells.

Basilar triangular shadows have been noted in roentgenograms of the lungs in fourteen children at the Hospital for Sick Children. Twelve of these were definitely associated with bronchiectasis. This represents a morbidity of only about 7 per cent of the cases of bronchiectasis studied in the period of observation. In all cases as far as could be determined, such shadows were produced by collapsed lower lobes of

the lung. There was no evidence in our cases and little in the literature to support Kerley's⁹ contention that such collapse usually occurs in an accessory lobe of the lung.

The shadows seen in our cases were permanent with one exception (case 5). No cases have come under observation such as those described by Findlay¹⁰ in which reinflation could be produced by deep breathing induced in his cases by inhalation of carbon dioxide. He states that this reexpansibility is the only proof of the atelectatic nature of the lobe. He explains however, that in long standing cases reinflation may be prevented by fibrotic changes. Bronchiectatic dilatation may be produced within two weeks of onset, as in case 11 so that reinflation would have to be done very early to be effective.

Fig 2 (case 7) —Appearance after injection of iodized oil.

The earlier observers of triangular basilar shadows, while still considering those produced by mediastinal pleurisy, commented on the larger amounts of sputum in these patients. There has been a tendency in more recent literature to stress the mildness of the bronchiectasis associated with lobar collapse, certain observers¹¹ calling it "dry bronchiectasis". A glance at the table will show that, while very early cases may not be attended by serious ill health, the disease is progressive, and ultimately all our patients had sputum. This became foul and abundant only when secondary invasion of

Fig 3 (case 7) —Lung obtained post mortem showing the collapsed lower lobe.

other lobes was present. The general health was seriously impaired in all either periodically or continuously.

The pathologic picture, aside from the very shrunk lobe, varied little from that already described by Erb.¹²

as found in bronchiectasis in children, the essential difference being in the relatively greater amount of collapse in these cases and the greater degree of fibrosis in the others

There is no difference in the etiology. Pneumonia is the commonest precursor in all types. The bacteriology, as in bronchiectasis, generally is not specific.

Fig. 4 (case 9)—Roentgen appearance Oct. 27, 1932, at 9½ years of age. M. B. was never well following pneumonia at 8 years of age. Bronchiectasis was diagnosed at 9 years and the patient died following lobectomy at 10 years of age.

COMMENT

Why does lobar collapse occur in some cases of bronchiectasis? Warner and Graham¹³ were able to produce such shadows in the lungs of dogs by occluding the bronchus to a lower lobe. It appears strange that if this were the important etiologic factor lobar collapse would not be a frequent result of

foreign body inhalation in children. A goodly number of such cases are seen every year, and until recently none of them have ever shown a triangular shadow in the roentgenogram. This occurred in case 11 but might in this case have been due to the pneumonia that preceded its development or to the mechanical irritation produced by the peanut that had been inhaled. Pulmonary collapse is frequently seen after aspiration of a foreign body, but it is either massive in type or irregular, rarely lobar. Bronchiectasis develops very quickly with bronchial occlusion by a foreign body not removed within a few days.

Some observers consider this lobar bronchiectasis to be congenital, basing their conclusions on the absence of pigment and of alveolar tissue. The latter is certainly small in amount but never entirely absent. Pigment was present in all our patients except the infant. None with lobar collapse dated their illness from birth. There was no evidence of its congenital origin.

Every case was examined bronchoscopically, and pathologic changes of the bronchial mucosa were apparent. The essential lesion is probably in the smaller bronchioles, which become occluded by secretion with resulting collapse. Dilatation is produced readily in the weakened bronchi by increased intrabronchial pressure. Whether such dilatations are compensatory, as Findlay suggests, is not certain. It may be that these cases are more commonly associated with a lobar type of pneumonia than are those without lobar collapse.

CONCLUSIONS

Basilar triangular shadows in roentgenograms of children's chests are due to lobar collapse.

Such collapse is usually associated with bronchiectasis. It is not pathognomonic of this disease but is very suggestive.

Lobar atelectasis is the result of infection or injury of the bronchial wall, with secretion and consequent plugging of the bronchioles.

ABSTRACT OF DISCUSSION

DR. JOSEPH STOKES, Philadelphia. I think every physician has been interested in this condition since it was brought so forcibly to our attention some years ago. I have been extremely interested in what Dr. Boyd has said. In the study of a group of children at Children's Hospital, Philadelphia, made chiefly by Dr. Rubin, we have been particularly interested in the fact that these children are mostly from the underprivileged classes, most of them being relief board cases, and it has seemed that this was directly associated with conditions of malnutrition and poor hygiene. In the infant, rickets might be an important factor in which there is improper development of the chest and also softening of the ribs, the inability to expand properly and therefore to overcome whatever collapse may have been present. As in congenital heart disease, these children should be transferred to a special group that can be studied thoroughly and watched closely over a period of years so that intercurrent infections may be kept at a minimum. The roentgen examination gives a great many more signs than physical examination, and I think there again it is important to remember that the x-rays should be considered a method of diagnosis as useful and as readily applicable as the stethoscope, and not left entirely to the roentgenologist. In actual clinical diagnosis, I think that very few signs are found in these cases. We have had a group of cases in the Children's Hospital which I should like to ask Dr. Boyd whether she has seen in Toronto, namely, infants with very marked dyspnea, cough, apparently what might be called capillary bronchitis and fatal bronchopneumonia. About six cases have come to necropsy. The characteristic finding has been dilated smaller bronchioles standing out well above the lung tissue. The appearance is that of a group of small white pipes standing out amidst the consolidated lung tissue. Apparently there is marked inflammatory reaction in the bronchial walls. I wonder whether in Dr. Boyd's opinion this type of case may result on recovery, in a future bronchiectasis. I should like very much to hear from Dr. Boyd about the question of treatment in these conditions.

DR. J. S. WALL, Washington, D. C. It is interesting to know that the name of Pasteur is associated so intimately with collapse. This is William Pasteur, an Englishman and not Louis Pasteur the Frenchman. In 1914 when he made his last contribution, he was recognized as the student who knew most about collapse. Dr. Boyd has leaned toward the theory of the plug origin, or obstructive origin, in producing collapse, and strangely enough Dr. Pasteur never acceded to the opinions of others that collapse was produced by a plug. His first studies were on collapse in diphtheritic paralysis and even in his retirement he still is unrepentant in recognizing the plugging of a

Fig. 5 (case 9)—Roentgen appearance April 21, 1933, at 10 years of age.

bronchus producing collapse. As I understood, in most of Dr. Boyd's cases there was a sequence of pneumonia, bronchiectasis and collapse, showing really that the dilatation of the tube and the presence in that tube of thick, viscid mucus probably had something to do with the production of collapse of the lung. Dr. Stokes said that in these cases very little could be learned from stethoscopic examination. That has often been my experience. The striking thing is the clinical picture of collapse cases in which a considerable area of lung is involved. These children look very much like children who are suffering from clinical acidosis with hyperpnea out of proportion to any somatic disturbance. Perhaps one gets a clue in that way. The second important clue is the dislocation of the heart toward the affected side and those two circumstances taken together even may point the way to diagnosis that would

later be confirmed by roentgen examination or sometimes, unfortunately, by autopsy. An interesting point in connection with collapse is the sequence of pneumonia, bronchiectasis and collapse that has been pointed out by Dr Boyd, and whether it might not be reasonable to believe that pulmonary collapse may even antedate pneumonia. Dislocation of the heart is a striking sign of pulmonary collapse and perhaps pulmonary collapse really does precede pneumonia rather than being the sequel to pneumonia.

DR. WILLIAM E. ANSPACH, Chicago. It seems to me that the important thing is not to wait to recognize the process at work in these cases until bronchiectasis is in full bloom, when the patient must run the risk of lobectomy, which so often fails to cure even though the patient survives the operation. It has

Fig. 6 (case 9).—Lung obtained post mortem. The right lower lobe previously removed by lobectomy showed a similar appearance.

been my privilege to watch a number of these cases from infancy to autopsy or beyond puberty. The triangular shadow in the roentgenogram, which must be depended on for the earliest diagnosis, is seen soon after the first symptom and as a rule is very small, smooth and homogeneous, not like the usual case of pneumonic consolidation. In the early period there is not the striped shadow or the shadow with scattered areas of decreased density so frequently seen in advanced cases of bronchiectasis. Cases coming to necropsy early after the onset of acute symptoms showed atelectasis of the lower lobe and there were no bronchial dilatations. Patients continuing to live, who retained their dense "triangular shadow," developed bronchiectasis. Bronchiectasis develops in a high percentage of children who have inadequate bronchial drainage. The roentgenologic sign of atelectasis is a warning of the presence of bronchial obstruction. Bronchiectasis can be avoided in a large number of cases by means of early bronchial aspiration and postural drainage. At the Children's Memorial Hospital where there has been an unusually large number of these cases, it has been interesting to note the predominance of right sided lower lobe collapse in children under 3 years of age. Additional collapse of other portions of the lung frequently followed and the mortality was high. Those who survived showed most often a left sided collapse and later left sided bronchiectasis.

DR. GLADYS L. BOYD, Toronto. I regret that I did not make my paper briefer so I could read it all. Perhaps it would have made some of the points clear that have been brought up for discussion. In reply to Dr Stokes about the poverty of these patients, most of them were from the poorer classes. I find bronchiectasis largely a disease of these classes and I do not think that patients whose bronchiectasis was associated with basilar triangular shadows were any worse off economically than others. Rachitic chest deformities have not been observed but only those produced by the pulmonary disease. On the

question of the recurrence of bronchiolitis, dilated bronchi in infants, I frequently observed that in cases particularly of influenzal pneumonia or associated with a good deal of bronchiolitis, the bronchi were dilated and sticking out sometimes with abscesses in the lungs as well. As far as treatment is concerned, in this group of cases it is pretty well limited to the treatment of bronchiectasis. I think, from the discussion that has gone on, that there are probably two groups of cases showing these shadows. In Dr Anspach's cases, which are far more numerous than my own they are of course mostly in young children and not necessarily associated with bronchiectasis, and reinflation of the lung could be produced. Specimens were obtained from four of my cases and it would be impossible from looking at these lungs to see how anything could reinflate them. As to diagnosing the shadow before the bronchiectasis occurred, in some of my cases the bronchiectasis has preceded development of the shadow. It is important to appreciate how rapidly bronchiectatic dilatation can occur in children. Ten days after the aspiration of the foreign body with no previous illness at all well marked grapelike dilatations have been frequently observed. In the one case in which a triangular shadow developed four days after aspiration of a foreign body the dilatations were well marked in the course of ten days. It has not been my experience that even in those cases reinflation could occur. They have been bronchiectasis from the start, and treatment has been more successful as far as clinical relief of the condition goes than it has in cases due to infection entirely, but it has not been any more effective in clearing up the dilatation.

OSTEOMYELITIS IN INFANCY

WILLIAM THOMAS GREEN, M.D.

BOSTON

Osteomyelitis in infancy differs in so many respects from osteomyelitis in older children that a separate consideration of the disease in children under 2 years of age is desirable. Until recently these distinctions have not been particularly emphasized in the medical literature. In 1932 Paschla¹ and in 1933 Green and Shannon² independently described certain of these differences, a knowledge of which is essential for proper treatment. At the Children's Hospital, Boston, more cases of acute osteomyelitis are seen in infants than in children from 2 to 12 years of age.

Osteomyelitis at Two Ages

| Children Under 2 Years of Age | Children Over 2 Years of Age |
|----------------------------------|---------------------------------|
| Streptococci 63 per cent | Staphylococci usually |
| Staphylococci 30 per cent | |
| Brief duration | Long duration |
| Rapid healing of wound | Slow healing of sinuses |
| Sequestration infrequent | Sequestration usual |
| Recurrences rare | Recurrences frequent |
| Lesions heal completely | Residual sclerosis of bone |

The usual conception of acute osteomyelitis is that of the syndrome as seen in older children—a disease generally due to *Staphylococcus aureus* (91 per cent), which after the acute phase usually adopts a chronic course of long duration, with sequestration, persistent sinuses and frequent recurrences. On the contrary, osteomyelitis of infancy is a disease more frequently due to *Streptococcus haemolyticus* in which, if the

² Green, W. T. and Shannon, J. G. Paper read in March 1933 before the Boston Orthopedic Club.

child survives the acute infection, the prognosis for complete and rapid recovery is excellent

In a previously reported statistical study of ninety-five cases seen at the Children's Hospital, from 1912 to 1932 inclusive Green and Shannon³ suggested that

1 Osteomyelitis in infancy was due more frequently to *Streptococcus haemolyticus* than to *Staphylococcus aureus* (63 per cent were streptococcic, and 30 per cent were staphylococcic)

2 The mortality rate of osteomyelitis in infancy was high, 21 per cent (This compares with 38 per cent in the series of Paschla¹ and 53 per cent in the series of Santi⁴) Under 6 months of age the mortality was even higher 44 per cent as compared to 13.4 per cent in those patients between 6 months and 2 years of age

3 Wounds healed rapidly after operation and were closed permi

thirty-nine were entirely healed clinically and by roentgenographic determinations, one case had been healed clinically for four years, although the roentgenogram suggested a residual lesion The final case, a recent one, has not yet healed

7 Deformities occurred in five of the forty-one cases examined in the end-result study Four of these were from secondary lesions of joints and one was from epiphyseal displacement and injury Of the deformities due to lesions of joints, two were of the hip with destruction of the head of the femur This was in accord with the observations of Paschla¹ who described septic joints and epiphyseal displacements as frequent complications of osteomyelitis in infancy

PATHOLOGY

In explanation of the differences of the disease in infancy, certain of the local manifestations of the infection must be considered as well as the fact that streptococcic osteomyelitis is more frequent than staphylococcic osteomyelitis *Staphylococcus* is liable to give rise to a more destructive process even in infancy The anatomic construction of the bones and certain physiologic characteristics of this age are factors in delimiting the character of the disease. This is discussed in detail in another publication⁵ and will be considered in summary fashion here

Osteomyelitis in infancy almost uniformly has its origin in the metaphysis as it does in older children Once the infection is under way it follows the path of least resistance⁶ (fig 1) In infants there is a minimal amount of cortical bone at the metaphysis, so that the spread to the subperiosteal space is extremely direct The periosteum, more loosely attached at this age, is dissected from the cortical bone, and the consequent subperiosteal abscess may rupture into the soft tissues without necrosis of the shaft This process goes on quite rapidly, and a secondary abscess may be present as soon as the second day after onset Gross sequestration is rare, what necrotic bone there is is usually absorbed rapidly Likewise the healing process goes on more rapidly in infancy, as may be seen in the illustrative cases

REPORT OF CASES

For consideration of the disease, three representative cases are presented

CASE 1—B G a white girl aged 1½ years was admitted May, 5, 1934 with an acute illness and pain in the right shoulder of two days duration Three weeks before the onset the infant had had an acute respiratory infection followed by otitis media

On examination the child was critically ill with a marked swelling of the right arm, maximal at the shoulder, and tenderness over the upper end of the humerus All motions of the shoulder joint were limited by muscle spasm, but there was no palpable fluid in the joint Fluctuation was suggested over the anterior aspect of the upper end of the humerus The temperature was 104 F Blood examination revealed 25,000 leukocytes

A diagnosis of osteomyelitis of the humerus was made.

The part was immobilized poultices were applied, and fluids were forced The next day the child had definitely improved and fluctuation was definitely present.

Fig 1—1, longitudinal section of tibia Osteomyelitis of three weeks duration in an infant aged 5 weeks The lesion started adjacent to the proximal epiphysis (A) at the metaphysis (B) and spread to the subperiosteal space at C→ where the cortical bone is minimal Note that subperiosteal new bone (E) extends the length of the shaft although involvement of the cortex does not extend beyond F B original lesion with necrosis of bone and exudate D periosteum Z diagrammatic sketch of Y showing mechanism of natural decompression Note the arrows

nently in an average of three months after the operation Frequently they healed in from four to six weeks

4 Sequestration was infrequent, gross sequestration occurred in only six of the ninety-five cases

5 Recurrences were rare, occurring in only two of ninety-five cases and in both instances consisting of brief drainage followed by final healing

6 Complete healing of the lesion in the bone was the rule In many instances the site of the lesion could not be recognized in the roentgenograms taken in an end-result study Of forty-one cases examined in this end-result study (not selected except as to service)

⁴ Santi E Osteomielite nei primi anni della vita Arch ital di chir 35 1 1934

⁵ Starr C L Acute Hematogenous Osteomyelitis Arch Surg 4 567 587 (May) 1922 Green and Shannon³

May 6, the day following admission, an incision with drainage of a secondary abscess in the soft tissue was done, the humerus was not disturbed. The wound was packed with petrolatum gauze and the extremity immobilized. Culture from the wound showed *Streptococcus haemolyticus*.

The temperature was normal on the third postoperative day and thereafter (fig 2). Roentgenograms on May 9, showed extensive destruction of the upper end of the humerus with

Fig 2 (case 1)—Clinical chart showing that the high temperature and rapid pulse on admission decreased and the patient's general condition improved on treating the child and immobilizing the extremity before operation. Operation: Drainage of a fluctuant abscess which was done at the optimum time. The temperature was normal on the third postoperative day.

displacement of the epiphysis (fig 3). Fourteen days later roentgenograms visualized definite healing with new bone (involucrum) surrounding the shaft throughout its length. The wound was healed in six weeks.

June 1, 1935, thirteen months after onset, the extremity was apparently normal, both to physical and to roentgenographic examination.

CASE 2—J. M. A., a boy aged 1 year, was admitted April 23, 1934, with an acute illness, sensitivity and swelling of the left lower extremity of six days' duration.

On examination the infant was acutely ill, pale and dehydrated, with an extremely swollen left lower extremity. The swelling and tenderness were maximal over the lower end of the femur. Motion at the knee was markedly limited by muscle spasm, but there was no fluid in the joint. Roentgenograms on admission were negative except for edema of the soft tissues. The temperature was 103 F. The white blood cell count was 26,000.

A diagnosis of osteomyelitis of the femur was made.

The extremity was immobilized and poulticed. Fluids were forced.

On April 24, the day after admission, an incision with drainage of a secondary abscess in the soft tissues was done; the femur was not disturbed. The wound was packed with petrolatum gauze and the extremity was immobilized with plaster. Culture from the wound showed *Staphylococcus aureus*.

The postoperative convalescence was uneventful; the temperature was normal by the fourth postoperative day. Roentgenograms two weeks after admission showed destruction at the lower end of the femur with an extensive involucrum about the lower two thirds of the shaft. The wound healed in two and one half months.

On final examination six months later, the extremity was clinically normal and roentgenograms showed little residuum (fig 4).

CASE 3—F. H., an infant aged 1 month, was admitted June 2, 1932, with an acute illness of two weeks' duration

associated with tenderness of the left shoulder. Four days before admission, swelling and redness of the shoulder were noted. Two days before onset a furuncle of the chin was noticed.

On examination the infant was moderately ill with swelling, tenderness and redness of the left shoulder and arm. There was definite fluctuation. Motions of the shoulder joint were limited. Roentgenograms on admission showed extensive destruction of the upper end of the humerus.

A diagnosis of osteomyelitis of the humerus was made.

The day after admission, incision with drainage of a secondary abscess in the soft tissues was done. The humerus was not disturbed. The wound was packed with petrolatum gauze and the part immobilized. Culture from the wound showed *Staphylococcus aureus*.

Roentgenograms, June 20, showed definite healing of the lesion with extensive involucrum surrounding the lesion. The wound was healed six weeks after operation.

June 1, 1935, three years after onset, the extremity was functionally normal on physical examination. Roentgenograms showed little evidence of the former lesion.

These cases may be considered as typical of the disease. Although any degree of illness may be found, the systemic manifestations are frequently quite severe and are usually noted before the presence of a local lesion is appreciated. The acute illness may often be ascribed to a respiratory infection, since antecedent respiratory infection is common. In our series of cases, 55 per cent gave definite evidence of antecedent infection, half of which were respiratory disorders.

Local sensitivity is soon evident. The child does not move the part and is irritated by handling. Swelling may be noted occasionally as soon as twenty-four hours after the onset, and soon becomes marked. It is frequently so diffuse as to be of little aid in localizing the site of the lesion. Redness is not a feature, nor is local heat particularly striking. If the lesion has been present for forty-eight hours or longer, thickening of

Fig 3 (case 1)—Osteomyelitis of the humerus—*Streptococcus haemolyticus*. Operation consisted of drainage of secondary abscess only. A, seven days after onset showing extensive destruction of the humerus with displacement of epiphysis. B, two weeks later showing considerable healing. C, one year after onset showing normal appearance. The patient is now clinically well.

the shaft adjacent to the epiphysis may be suggested, and soon thereafter palpable deep fluctuation may be recognized. Tenderness at the metaphysis, although more difficult to elicit in infants than in older children, is a determining factor in recognizing the exact site of the lesion.

ROENTGENOGRAPHY

It is our constant practice to take roentgenograms although they are of little positive aid in the diagnosis, in that they do not demonstrate the lesion until from seven to twelve days after the onset. However, they may be helpful in various ways, they may demonstrate the presence of scurvy, syphilis, or an osteomyelitic

Fig. 4 (case 2)—Acute osteomyelitis of the femur—*Staphylococcus aureus*. Operation consisted of drainage of the secondary abscess only. A three weeks after onset showing destruction of the lower end of the femur with extensive involucrum. B six months later nearly healed. The patient is now clinically well.

lesion of longer duration than the history suggests. The visualization of the soft tissues may be helpful.

Roentgenograms taken to observe the course of the disease are valuable and are very illuminating. Frequently they exhibit extensive destruction with involucrum surrounding the length of the shaft and suggest that gross sequestration will surely occur. One is amazed in subsequent roentgenograms to notice rapid healing without sequestration.

DIFFERENTIAL DIAGNOSIS

Osteomyelitis must be suspected in any infant with an acute illness associated with a sensitive extremity. Other conditions to be considered particularly are abscess (subfascial abscess), septic joint, scurvy and syphilis.

Septic joints are common in infancy. Palpable fluid in the joint with extreme muscle spasm and local sensitivity suggest septic joint. It must be remembered that an effusion into a joint not infected may exist from an adjacent osteomyelitis and that septic joints secondary to osteomyelitis are more common in infancy than at other ages.

Deep abscesses are common in infancy and often are impossible to differentiate from osteomyelitis previous to operation. If the physical signs are maximal away from the metaphysis, it is suggestive of abscess.

Scurvy and syphilis may be recognized by history, multiplicity of lesions, and roentgenograms. Tuberculosis is not difficult to differentiate.

TREATMENT

In acute osteomyelitis of older children there is considerable debate as to the treatment to be adopted—the time of operation, the type of operation and subsequent care. Based on the idea that progressive infection within rigid walls produces increased necrosis, it is, I believe, a prevailing although not universal feeling that operation to “decompress” the infection should be carried out at the earliest possible moment, preferably in the form of a window at the site of the lesion. Whatever the treatment, a long drawn out complicated course is frequent.

In infancy I believe that the indicated therapy is more definite. The prime consideration is the treatment of the acutely ill child, not the local lesion. If the infant survives the acute illness, the disease will be brief, with residuum in the bone unusual. With these considerations in mind we have been able to reduce our mortality in the cases treated from 1931-1934 inclusive to 6.6 per cent. There have been only two deaths in thirty cases and both of these were of infants under 2 months of age who had diffuse sepsis.

Early drainage of the bone does not decrease the amount of destruction nor does it limit the systemic manifestations. On the other hand poorly timed, extensive surgery jeopardizes the child's life. There is no haste in performing an operation and operative procedures must be minimal. The infant should be in the best possible condition at the time of the procedure.

Fig. 5 (case 3)—Osteomyelitis of humerus in child aged 1 month. *Staphylococcus aureus*. Operation consisted of drainage of the secondary abscess. A one month after onset showing destruction with surrounding involucrum. B three years later apparently normal.

Unless an abscess is palpable and the child is in excellent condition on admission, it is our custom to immobilize the part, apply poultices and give the indicated supportive treatment. Usually the child's condition improves (fig. 2), localization of the process occurs, and the exact site of the lesion may be recog-

nized Frequently we allow a palpable abscess to form before an operation is done This occurs quite rapidly

At operation it is not necessary to carry out a procedure on the bone if the secondary abscess is adequately drained At any rate, the operation should not be complicated in order to drain the bone A small window in the bone is permissible but not essential, "the less done, the better" The wound is packed with petrolatum gauze and immobilized, usually in plaster The first dressing is done in ten days and the wound is repacked at weekly intervals The interval of ten days before the first dressing allows granulations to form so that the wound is no longer sensitive

Usually the wound is entirely healed in from four to eight weeks

The reason for adopting this treatment is that there is less immediate danger to the infant and at least as good a final result as is obtained by any other method It must be understood that there can be no absolute statements about treatment individual decisions must be made on individual patients

CONCLUSION

Osteomyelitis of infancy is a disease of relatively brief duration, with sequestration and recurrences rare and residual lesions in the bone unusual, if the child survives the acute illness

The mortality rate may be reduced by "treating the child," by allowing localization and by carrying out the minimal surgical procedures

300 Longwood Avenue

ABSTRACT OF DISCUSSION

DR FRANK R OBER Boston Osteomyelitis in infancy is an emergency problem, not as to local condition but as to the life of the child Twenty years ago at the Children's Hospital in Boston, the plan of treatment was to consider the condition an emergency This involved an immediate operation on admission of the patient and removal of a piece of bone, tunneling the shaft The result of such a procedure was a high mortality rate Postoperative treatment consisted of frequent dressings containing some antiseptic solution I became convinced that these frequent dressings which disturbed the patient and caused bleeding from the wound surfaces, did no good Frequent dressings increase the toxic condition of the patient In those days the mortality in infants was around 50 per cent but as we began to be more conservative in the matter of dressings, the mortality rate decreased It was not until Dr Green began his study of osteomyelitis however, that any of us became aware of the fact that no matter what was done in the way of surgery, the reaction of the bone was practically the same Of these ninety-five cases which Dr Green reports only six show sequestration If a child is very ill and his temperature drops the results are not good if the operation is not performed fairly soon These infants should be watched very carefully and a definitive operation performed when the general condition of the child is at its best Usually the operation means as Dr Green has pointed out only a simple incision and drainage of the abscess This abscess should be packed down to the bone and dressed only once a week In every case of osteomyelitis it is important that the wound heal from the bottom Dr Green is to be commended for bringing to attention that osteomyelitis in infants less than 2 years of age is a different disease from that in the older child

DR WILLIAM T GREEN Boston I have considered the mortality during the past five years to be very low The two deaths in the thirty patients treated during this period have been in infants less than 6 weeks of age who presented multiple septic lesions at the time of admission There has been one deformity in this time and that was due to epiphyseal displacement The epiphysis was displaced at the time of admission I believe that if enough patients are treated there will be a

certain number of deformities and a certain number of deaths I feel that I have been fortunate during the last five-year period and believe that a slightly higher incidence of deformities may be anticipated and a slightly higher mortality rate rather than a lower one I think that immobilization is an important item in preventing deformities

TUBERCULOUS LYMPHADENITIS

SECONDARY TO INCONSPICUOUS HEALED TRAUMATIC CUTANEOUS TUBER- CULOUS LESIONS

B N CARTER, MD

AND

JACOB SMITH, MD

CINCINNATI

During the past twelve years at the Cincinnati General Hospital, four cases of proved and three of probable traumatic inoculation tuberculosis of the skin with metastasis to regional lymph nodes have been seen Instances of this condition constitute a very definite but quite unfamiliar group, and for this reason our cases are being reported The outstanding adenopathy in each case has usually overshadowed the primary focus With a more accurate knowledge of the pathology and clinical course a more frequent identification of new cases should result

Very little has been written about healed traumatic tuberculous lesions of the skin with regional lymphadenopathy Tscherning (quoted by Stokes¹) in 1888 reported the case of a servant of a tuberculous patient who injured a finger with a fragment of a sputum cup Subsequently, lymphatic involvement occurred The finger was amputated and the involved glands were excised, following which the patient recovered Klebs,² in his book published in 1909, mentions extensive tuberculosis of the inguinal glands in an infant resulting from a slight prick of the thigh with a safety pin

Ceremonial circumcisions occasionally lead to a fatal tuberculosis among the poor Jewish and Mohammedan children Holt³ in 1913 collected forty-one such cases, sixteen of which had a fatal termination

From time to time sporadic articles have appeared, but in each the reported primary lesions have always been well defined However, two cases of cutaneous tuberculosis associated with trauma were reported by Chancellor⁴ in 1914 In one case, a pin which had been carried between the lips of a tuberculous uncle was the offending agent and the method of inoculation was a scratch on the cheek, in the other, the playful bite of a nurse produced the focus on the cheek, which was followed by regional lymphadenopathy, and later innumerable tubercle bacilli were demonstrated in the nurse's sputum In 1923 Nixon and Short⁵ described four cases, three following trauma The most recent article is by Stokes¹ in 1925 with a report of twelve cases These will be referred to later

REPORT OF CASES

CASE 1—C C, a white boy, aged 11, in the Cincinnati General Hospital from March 22 to April 18 1934 ran a nail through the left palm in the web between the first and second fingers two years before admission, and later a lump was noticed in the left axilla. The patient was seen in the surgical clinic two months later, at which time a small nodule was found in

Fig 1—Section through the excised healed lesion on the toe in case 4. Note the intact skin over the focus in which typical tuberculous granulation tissue with giant cells can be seen.

the healed scar at the site of the puncture wound. It measured 6 mm in diameter and lay deep in the web. This was excised in the outpatient clinic and found to have a caseous center. The microscopic examination revealed tuberculosis. The wound healed rapidly but the axillary glands became larger, more tender and fluctuant. Two weeks later, 4 cc. of pus was aspirated. The smear was negative for tubercle bacilli, and the guinea-pig died too soon to demonstrate tuberculosis. The tuberculin test was four plus. A roentgenogram of the chest revealed only calcification at the hilus. A sinus then formed in the axilla and drained for six months. The size of the axillary nodes remained stationary.

Seven weeks before entry into the hospital the nodule reappeared in the palm and the axillary mass again became larger and more tender.

At the base of the web between the first and second fingers of the left hand on the palmar surface there was a slightly tender subcutaneous nodule, 1 cm in diameter, firm but movable. In the left axilla was an irregular hard moderately tender mass 4 by 3 by 1.5 cm, high in the apex. It was freely movable and there was no demonstrable sinus.

Radical excision of the glands and of the primary focus was done.

The pathologic diagnosis was tuberculosis of the skin and glands.

The patient was seen one year later, at which time there was no evidence of any recurrence, either in the web between the fingers or in the axilla.

CASE 2—B S, a white girl aged 14 followed in the outpatient surgical clinic of the Cincinnati General Hospital from May 5 to May 26 1932 cut her right hand on the palmar

surface at the proximal part of the thenar eminence while washing dishes, about eight months before coming to the outpatient dispensary. This was just a superficial laceration, but it did not heal for more than two weeks. During this time it drained a moderate amount of pus. It remained a well healed lesion, but three months later the patient noticed a hard tender lump in the right axilla. This disappeared but then reappeared about one month later and from that time continued to enlarge.

There was a healed scar on the right thenar eminence. In the right axilla there were two masses, one 3 by 2 cm., the other 5 by 7 cm. One was firm, slightly tender and irregular without any fluctuation or evidence of secondary infection, the other was fluctuant and appeared as though ready to break down. A roentgenogram of the chest was negative.

Fifty cc of a grayish fluid was aspirated. The smear was negative for tubercle bacilli, but the guinea pig was positive. The healed wound was then excised and the larger glands were drained by repeated aspiration. When last seen three weeks after the first visit the operative wound on the thenar eminence was healed and the glands in the axilla were decreasing in size.

The pathologic diagnosis was tuberculosis of the skin. The clinical diagnosis of tuberculosis of the axillary glands was confirmed by guinea-pig inoculation.

The patient was seen two years later in the gynecologic clinic, where a note was made that the abscess had remained healed.

CASE 3—G D., a Negro boy, aged 13, in the Cincinnati General Hospital from Jan 10 to Jan 28 1928 struck his right

Fig 2—Section from the femoral glands in case 4.

femoral region six months before while working on a vegetable wagon. Soon after a lump appeared there and two weeks after the original trauma a sinus opened and drained. This sinus never closed. The drainage was always scanty. The patient was not questioned about trauma to his leg or foot.

A small white nodule was found at the base of the second toe. The right femoral nodes were enlarged and irregular. There were no sinuses but two large ulcers were situated on the most prominent regions.

Radical excision of the glands and of the healed scar on the foot was done. The pathologic diagnosis was tuberculosis of the skin and glands. The patient did not return.

CASE 4—W H, a Negro boy, aged 9 in the Cincinnati General Hospital from Feb 10 to April 2, 1930 noticed a swelling in the left groin three months before. One month later this was incised by a physician and following this there was a moderate amount of purulent drainage. There was never any pain associated with it, nor history of any injury to the foot or leg.

A small hard healed lesion was found on one of the toes. In the left femoral triangle was an ulcer 4.5 by 1.5 cm with a dirty granulating base. Medial to it was an indurated mass which was not fluctuant 5 by 3 cm in size.

Radical excision of the glands was done and wedge excision of the healed scar on the toe.

The pathologic diagnosis was tuberculosis of the skin and glands (figs 1 and 2).

The patient did not return.

CASE 5—J T, a white boy, aged 10 in the Cincinnati General Hospital from Nov 1 to Nov 22, 1923 ran a nail into his left heel four months before admission, and a few days later the heel became red and swollen. His father opened it and some

three-story window three months before and struck his left knee. It became quite swollen and remained so for five weeks. Following this a tender lump appeared in the left femoral region. This persisted and a sinus developed.

The knee was normal at the time of admission into the hospital. No skin lesions, healed or otherwise could be demonstrated. There were large nodes in the left femoral region, with a draining sinus.

Radical excision of the glands was performed.

The pathologic diagnosis was tuberculosis of the glands.

The patient did not return.

COMMENT

Tuberculosis cutis following trauma is frequently overlooked, especially if the lesion is apparently healed. Tuberculosis of the skin may be initiated in several ways: (1) through the blood stream, (2) by the lymphatic route, (3) by extension from another focus within the body, and (4) by direct inoculation. The type of infection of particular interest is that occurring by direct inoculation associated with trauma, and healed at the time the patient is first seen. Experimentally

Summary of Cases

| Case | Race | Sex | Age | Date | Etiology (Primary Focus) | Glands | Other Tuberculous Glands | Diagnostic Procedures | Operation | Pathologic Condition | Follow Up |
|------|-------|-----|-----|---------------------|---|----------|-----------------------------|---|------------------------------|---------------------------------|----------------------------|
| 1 | White | ♂ | 11 | 3/22/34 4/18/34 | Traumatic inoculation of web of hand by nail | Axillary | None | Roentgenogram of chest negative | Excision of glands and focus | Tuberculosis of skin and glands | No recurrence 1 yr later |
| 2 | White | ♀ | 14 | 5/5/32 5/20/32 | Traumatic inoculation of thenar eminence of hand by broken dish | Axillary | None | Roentgenogram of chest negative | Excision of focus | Tuberculosis of skin | No recurrence 2 yrs later |
| 3 | Negro | ♂ | 13 | 1/10/28 1/23/28 | Small white nodule at base of 2d toe (no known trauma) | Femoral | None | Roentgenogram of chest negative | Excision of focus and glands | Tuberculosis of skin and glands | None |
| 4 | Negro | ♂ | 9 | 2/10/30 4/2/30 | Small lesion on the toe (no known trauma) | Femoral | None | Tuberculin 4 plus | Excision of focus and glands | Tuberculosis of skin and glands | None |
| 5 | White | ♂ | 10 | 11/1/23 11/22/23 | Traumatic? inoculation of heel (not proved) | Femoral | Enlarged hilar glands | Roentgenogram of chest negative tuberculin negative | Excision of glands | Tuberculosis of glands | No recurrence 12 yrs later |
| 6 | White | ♂ | 10 | 10/21/27 1/17/28 | Traumatic? inoculation of foot (not proved) | Femoral | Enlarged mediastinal glands | Roentgenogram of chest negative tuberculin negative | Excision of glands | Tuberculosis of glands | None |

bloody pus was obtained. The wound healed rapidly then, and the child was able to walk on it without any pain. One month later, a small lump appeared in the left groin. The mass was slightly reddened and gradually increased in size but was never painful.

There was a healed scar on the heel and a mass the size of half an orange in the left femoral region, quite red and fluctuant in its lower portion.

Radical excision of the glands only was performed.

The pathologic diagnosis was tuberculosis of glands.

The patient was seen twelve years later. There was no demonstrable recurrence in the femoral region. The scar on the heel could not be demonstrated. The patient stated that he had been perfectly well.

CASE 6—H M, a white boy, aged 10, in the Cincinnati General Hospital from Oct 21, 1927 to Jan 17, 1928, had had an injury to his right foot but was unable to give accurate information as to the time of injury in relation to the subsequent lymphadenopathy. The wound healed slowly but lumps appeared 'later' in the right femoral region. These broke down and drained and were draining at the time of admission.

The scar was not described in the history. There was marked enlargement of the right femoral nodes with a sinus draining thick white pus. The local area was quite red. There was no fluctuation present.

Radical excision of the glands only was performed.

The pathologic diagnosis was tuberculosis of the glands.

The patient did not return.

CASE 7—W Z, a Negro boy, aged 6 in the Cincinnati General Hospital from March 23 to May 20, 1926 fell from a

transcutaneous tuberculous inoculation can be produced without abrasion or interruption in continuity of the skin, if virulent cultures or sputum teeming with tubercle bacilli is placed on normal skin that has been vigorously massaged or just shaven. Babes and Riegler, Courmont and Lesieur, Fraenkel, Takeya and Dodd (quoted by Calmette⁶) have thus produced tuberculosis in guinea-pigs, rabbits and cattle. Furthermore, transcutaneous infection may not leave behind any residuum, and regional lymphadenopathy does not necessarily follow as a consequential phenomenon.

A study of our first two cases immediately focuses attention on three outstanding features of the primary lesion with its regional adenopathy: (a) The initial causative factor was, in each case, some form of trauma, producing an open wound. In one instance it was a puncture wound by a nail, in the other a laceration secondary to a broken dish. (b) In both, the primary focus when first seen was healed. This point cannot be stressed or emphasized too strongly, as in four of the remaining five cases the site of apparent inoculation was completely healed at the time of admission to the hospital. In two of these it was excised and proved tuberculous, or a total of four proved healed foci, in the remaining two, just a passing note was made in the

⁶ Calmette, Albert. *Tubercle Bacillus Infection and Tuberculosis in Man and Animals*. Baltimore: Williams & Wilkins Company, 1923.

history of one and in the other no consideration was given it (c) The interval of time between the traumatic inoculation and the appearance of regional lymphadenopathy was of some length, in one case three months, in the other just "later" Another case (J T) had a time interval of one month The most prominent feature of this condition is the adenopathy, and it is usually this that brings the patient to seek medical attention Since there is such a relatively long interval between the time of skin inoculation and the appearance of regional adenopathy, the possibility of a primary focus is frequently overlooked

In completing the analysis of our remaining five cases, little can be added to the foregoing Each contains one or more features of the first two typical cases and merely reemphasizes the points mentioned

The lymph glands that may become involved are the cervical, axillary and inguinal groups Tuberculosis of the cervical nodes, or "scrofula," is an infrequent sight now because of careful supervision of dairy herds and the widespread removal of enlarged infected tonsils In this series there were no cases of cervical adenitis secondary to cutaneous lesions Femoral lymphadenopathy was present in five of the cases and there were only two with involvement of the axillary nodes All but one case (B S) were treated by radical excision and were proved tuberculous on microscopic section

Roentgenograms of the chests of two patients demonstrated enlarged mediastinal glands, but in none was there any further involvement of any other group of lymph nodes other than the regional

According to all writers, the human form of the tubercle bacillus is the one most commonly encountered in cutaneous lesions Unfortunately we have no bacteriologic studies in our cases

Very little data can be obtained from our cases as to the clinical pathology of the primary lesion However, Stokes¹ in 1925 reported ten cases of undoubted and two of probable inoculation tuberculosis of the skin with an excellent description of the usual traumatic inoculation site Of his ten proved cases, five were on the face, three on the forearm and hand, and two on the foot Only three occurred in children, aged 2, 4 and 5, three at the ages of 13, 16 and 17, and four in adults The sex was evenly divided, five females and five males In our series there were no adults, the patients all being children between the ages of 6 and 14, six males to one female, four white and three Negroes

Of particular interest are several of Stokes' cases illustrating features of paramount importance from the diagnostic and therapeutic standpoints In his first case there were present large cervical and preauricular glands with multiple draining sinuses Above the right malar prominence there was a small depressed scarlike lesion about 1 cm in diameter, around which a few apple-jelly nodules could be demonstrated in a faintly pink areola "This apple-jelly nodule is a tubercle in the deeper layers of the corium or in the fat which, though ordinarily invisible, can be detected by expressing the blood from the tissue with a glass spatula These nodules are not absolutely characteristic, however, they are a helpful guide to diagnosis and are the first feature to arouse suspicion at a site of traumatic inoculation"

In two of Stokes' cases there was a recurrence of adenitis following excision No primary focus had been identified After the recurrence, search was made and an inconspicuous focus found These were excised, with subsequent healing, which was permanent "These cases furnish excellent examples of the continuous

vicious activity of the 'feeder focus' and the benefit derived from its removal" Another of his patients received rather intensive roentgen therapy to the primary lesion but without effect After excision, activity was demonstrated indicating the ineffectiveness of the roentgen ray in dealing with the primary site of inoculation

CONCLUSIONS

1 Tuberculous lymphadenitis may occur secondary to a focus of a traumatic tuberculous inoculation in the skin

2 The interval between traumatic inoculation and the appearance of regional lymphadenopathy may be of such length that the primary lesion may be healed and consequently overlooked

3 Because of the inconspicuousness of the primary lesion, very little consideration is directed toward it

4 Chronic lymphadenopathy subsequent to even remote trauma of an extremity should immediately arouse suspicion and incite careful search for a tuberculous cutaneous focus This is especially important in the study of solitary involvement of the axillary, epitrochlear and inguinal lymph nodes

5 Surgical excision of the site of inoculation, even though healed and apparently innocuous, should precede any active medical or surgical procedures directed toward the adenopathy

PROGRAM FOR TUBERCULOSIS CONTROL IN PUERTO RICO

EDUARDO GARRIDO MORALES, M.D., DR.P.H.
Commissioner of Health
SAN JUAN, P. R.

Tuberculosis, for the year ended December 1934, ranked as the first cause of death in Puerto Rico In many other countries the death rate from this disease, especially during the past twenty-five years, has had a downward trend, but in Puerto Rico it has shown a steady rise, demonstrated by the average annual rates of 170.5 in 1910-1914, 201.4 in 1920-1924 and 295.3 in 1930-1934 per hundred thousand of population The last rate is approximately five times the death rate from tuberculosis in the United States registration area

Among the important factors presumably responsible for the increase of the tuberculosis mortality in Puerto Rico, cognizance should be given to overcrowding in urban districts as a result of migration of families from rural areas to city slums, the lack of employment which brings overcrowding in dwellings, the relatively low economic status of the island population and the lack of hospital facilities for the isolation of the tuberculous

According to studies carried out by the Insular Department of Health, the tuberculosis mortality in the island is 17 per cent higher in women than in men, 19 per cent higher in the Negro than in the white race and 84 per cent higher in the urban than in the rural districts Approximately 68 per cent of children under 15 react positively to the intradermal tuberculin test the incidence of positive reactors being 37 per cent higher in urban than in rural districts Clinical evidence and autopsy results have revealed that the chronic fibrocaseous type of the disease is the predominant form Pulmonary tuberculosis is responsible for 97 per cent of all deaths from this disease Human tuberculosis of bovine origin is comparatively rare

Read at a meeting of the Pan American Medical Association held at the Antituberculosis Hospital Rio Piedras P. R. July 29 1935

In view of the importance of tuberculosis as a health problem in Puerto Rico, the present administration of the health department formulated a program to intensify its efforts to control the disease. This program included the following:

(a) Intensification of the tuberculosis work in the dispensaries of the public health units, which are the case finding agencies under the health department.

(b) Isolation of the largest possible number of cases of open pulmonary tuberculosis in four district hospitals with a total capacity of 1,500 beds, adequately equipped for giving proper treatment.

(c) Organization of ten antituberculosis centers, each in charge of a tuberculosis specialist, to whom cases are referred for diagnosis and selection before admission to the hospitals.

These centers also serve as collapse clinics for the application of pneumothorax treatment to patients after they leave the hospitals.

(d) Two traveling clinics to provide x-ray facilities and pneumothorax treatment for rural municipalities.

(e) An educational campaign, especially through the public health units and the public schools of the island.

(f) Intensification of preventive measures by increasing the number of rest rooms in the public schools and increasing the number of preventorium beds, activities under the management of the Commission for the Prevention of Tuberculosis in Children of School Age.

(g) Eradication of tuberculosis in cattle.

TUBERCULOSIS DISPENSARIES WITH VISITING NURSES

Before 1934 there were twenty health units in the island, comprising thirty-eight municipalities and serving a population of 1,054,575, or 68 per cent of the island population. At present there are fifty-four municipalities served by health units, with an aggregate population of 1,300,767. Each health unit has a full-time medical officer, one or more public health nurses, one or more sanitary inspectors, a clerk-microscopist and a caretaker. Tuberculosis control is an important feature of the work of these health units. At present they have a staff of thirty full-time and fifteen part-time physicians and 154 visiting nurses. There are in Puerto Rico fifty-eight tuberculosis dispensaries, attached to the public health units of fifty-four municipalities. At least one fourth of the time of the personnel of these public health units is being devoted to tuberculosis work.

TUBERCULOSIS HOSPITALS

We consider the isolation of open cases of tuberculosis among the most urgent measures in a country, such as Puerto Rico, where tuberculosis mortality is excessively high and where the standards of living of a large proportion of the population are so low that effective isolation of the tuberculous patient in the home is out of the question in most cases.

Previous to the year 1934 there were 550 hospital beds available in the insular institutions for the isolation of tuberculous patients. The average yearly number of deaths from tuberculosis during the last five years has been 4,500. According to the standards of the National Tuberculosis Association at least one bed per annual death is required for an effective antituberculosis campaign. Considering these facts, funds were obtained from the Puerto Rico Emergency Relief Administration for the construction of ten hospital units with a total capacity of 1,000 beds. A campaign was organized to raise funds for their equipment, and the insular

legislature, realizing the seriousness of this problem, has provided adequate funds for their maintenance through a lottery bill, approved in the last session of the insular legislature.

Although the number of beds available at present in insular institutions for the isolation of tuberculous patients is only about one third of what it should be in accordance with the recognized standards of one bed for each annual death from this disease, this represents, nevertheless, a large effort in the control of tuberculosis. It is proposed that the hospital beds available will be used to a large extent for the elimination of the open cases through the use of such modern measures of collapse therapy as will convert the positive sputum case into a negative case in as short a time as possible.

ANTITUBERCULOSIS CENTERS AND TRAVELING CLINICS

The Antituberculosis Center, which is a new feature added to the tuberculosis work in Puerto Rico, is an important part of our program. Each center is in charge of a physician specialized in tuberculosis work and is well equipped with fluoroscopic and other facilities for the diagnosis and treatment of tuberculosis.

The specialist in charge of the center serves as a consultant to whom the health officers may refer difficult cases for diagnosis. He also administers pneumothorax treatment to ambulatory patients after they leave the hospitals.

At present four centers are functioning. Six others will be opened during the present year. A traveling clinic, with x-ray equipment and facilities for pneumothorax treatment, is also available for rural municipalities.

It is proposed that each center shall take care of 100 pneumothorax cases besides giving expert advice to health officers in obscure cases. In this way 1,000 additional open cases of pulmonary tuberculosis can be kept from spreading infection in the home and together with the 1,500 isolated in the four district hospitals will make a total of 2,500 cases under control.

EDUCATIONAL ACTIVITIES AND PREVENTIVE MEASURES

The common dictum that "An ounce of prevention is worth a pound of cure" applies in tuberculosis work as well as in any other transmissible disease. Unfortunately, the value of preventive measures in tuberculosis work in Puerto Rico is limited by the relatively poor economic status of the island population and the exceedingly low standards of living of the great majority of the inhabitants. However, the education of the people in the modes of spread of the disease and the essential features of prevention are carried out through conferences by health officers and nurses, and by the distribution of pertinent literature and pamphlets. A moving picture has recently been prepared, which will also be used in connection with educational activities.

The number of rest rooms in the public schools as well as the number of preventorium beds have been almost doubled this year. Undernourished children, especially contacts of tuberculous patients, are taken care of in these rest rooms.

ERADICATION OF TUBERCULOSIS IN CATTLE

Although human tuberculosis of bovine origin is not a serious problem on the island because of the habit of boiling the milk before use, nevertheless the danger of its spread has increased with the recent tendency to use raw milk brought about with the introduction of electrical refrigeration in the homes of the middle class.

On this account a cooperative plan for tuberculosis eradication in cattle has been approved between the federal and insular departments of agriculture and the insular department of health. There are at present seven veterinarians doing intensive tuberculin tests on the island, and 29,380 cattle have already been tested, of which 731, or 2.4 per cent, have reacted positively and have been slaughtered.

The federal government pays an indemnity of \$50 for each slaughtered animal of pure breed and \$25 for each animal of mixed breed that is slaughtered.

Since experience has demonstrated that positive reactors are found to a large extent among imported breeds of cattle, the present law provides that imported cattle must have a certificate from a veterinarian accredited by the federal government, to the effect that they are free from tuberculosis.

SUMMARY

The tuberculosis program in Puerto Rico has been formulated on sound epidemiologic grounds in an effort to protect the community rather than the individual case.

The search and location of the largest number of open cases through the dispensaries in the public health units, their isolation in adequate hospitals until they have been changed from sputum positive to sputum negative by means of collapse therapy, and the continuation of refills in well equipped antituberculosis centers in order to keep the patients free of tubercle bacilli in the sputum, together with some degree of education of the public and the eradication of tuberculosis in dairy cattle, are measures in which we have great hopes.

Clinical Notes, Suggestions and New Instruments

PNEUMOCOCCIC MENINGITIS • REPORT OF A CASE WITH RECOVERY FOLLOWING CISTERNAL DRAINAGE

P. R. MEYER, M.D., PORT ARTHUR, TEXAS

It has always been the general impression that pneumococcal meningitis is practically hopeless. The more one searches the literature, however, the more cases of recovery one finds. The methods of treatment of this condition have been varied. Those with successful recoveries feel that their form of treatment was responsible for the happy conclusion. For example, Weinberg¹ used potassium permanganate following the suggestion of Nott. Reveno and McLaughlin² used Felton's serum alone, intravenously, intraspinally as well as intrathecally, although mentioning the use of the antipneumococcus serum combined with ethylhydrocupreine hydrochloride (optochin). Lynch³ also used Felton's serum and McAuley and Hilliard⁴ report a case in which Felton's serum was used. Eichelbaum⁵ used spinal drainage, lavage and intraspinal injections of antipneumococcus serum, for which he concluded that recovery in his case was responsible. Mella⁶ used subarachnoid lavage and ethylhydrocupreine with good results. Roussel⁷ used large

doses of methenamine. Rohrbach⁸ used Felton's serum in a case of type IV, with recovery. Shuller⁹ in reviewing the literature, refers to five recoveries in which treatment was given by various means besides those just mentioned, one was treated with intracarotid injection of colloidal solution of iodine and acriflavine base, in another, Homton's antibody solution intramuscularly and intradermally, and ethylhydrocupreine hydrochloride were used. His own patient was given Mulford's pneumococcus antibody solution. Ashmun¹⁰ used ethylhydrocupreine hydrochloride intraspinally and acriflavine base in his two cases. Kolmer¹¹ believes that when pneumococci are found in the spinal fluid, pneumococcus antibody solution or antipneumococcus serum should be given intravenously and that the intraspinal injection of a mixture of 25 cc. of pneumococcus antibody solution, or polyvalent antipneumococcus solution, with 1 cc. of 1:100 solution of ethylhydrocupreine hydrochloride should be instituted after removal of the fluid. Intracarotid injection of the same mixture should also be given. He states, however, that in diffuse meningitis continuous and even surgical drainage should be used. Harkavy¹² used Felton's serum and considers it responsible for the sterilization of the spinal fluid and subsequent recovery. Globus and Kasanin¹³ used only repeated lumbar and cisternal punctures, although they feel that serum therapy does have its place. Amessee¹⁴ reports that his patient received only a daily spinal drainage. Bedell's¹⁵ patient also was treated without the use of serum and with cisternal and lumbar drainage and irrigations, however, in her case a rubber drainage tube was inserted into the cisterna magna for continuous drainage.

As to the type of pneumococcus that is the causal agent, Bauer and St. Clair¹⁶ report type III to be most common in cases following otitis media, and type IV in cases without a history of otitis media. Unfortunately in the case to be reported the organism was not typed.

REPORT OF CASE

J. R. M., aged 5 years, became ill, Monday, March 4, 1935, and complained of headache and fever. The past history and family history were irrelevant. The physician who saw the child diagnosed a digestive upset. Fever continued to be high and the child began to vomit. March 6 the patient was seen by another physician, who also diagnosed the condition as a digestive disorder. When seen by me the morning of March 7 the temperature was 105.4 F. The child was alert and complained of a slight headache, otherwise there was no discomfort. As I entered the room the patient had just finished drinking a glass of water. I was sitting in the chair about 2 feet from the bed when the child suddenly and without any effort vomited. The force was so great that very little fell to the floor, the majority reaching my chair.

Physical examination revealed only slight anterior nuchal rigidity, an acutely reddened pharynx, an absent Babinski reflex, absent knee jerks, and positive Brudzinski and Kernig signs, otherwise the examination was negative. A spinal puncture was made and a thick cloudy fluid under some increase in pressure was removed. This fluid was sent to the laboratory and hospitalization was advised.

The fluid on examination had a cell count of 3,500, globulin 4 plus and no sugar reduction but no organisms were found. A culture of the fluid was taken, but subsequent examination failed to reveal any organisms. Fifteen cubic centimeters of meningococcus serum was given intraspinally after removal of

more fluid, and 15 cc was given intravenously. The child was also given 300 cc of citrated whole blood by transfusion. The fluid examination made after admission to the hospital showed a cell count of 3,100, globulin increased, and no sugar. A smear of fluid revealed many pus cells, occasionally gram-positive intracellular diplococci were found. Culture of the fluid March 8, revealed gram positive diplococci and short chain streptococci (contamination not excluded). The white blood count was 13,900, neutrophils 75 per cent large lymphocytes 3 per cent, small lymphocytes 22 per cent. Analysis of the urine revealed a specific gravity of 1.020, a distinct trace of albumin no sugar, a few pus cells, and many fine and coarse granular casts.

On spinal puncture, made by Dr C M Beavens the fluid was cloudy and under increased pressure. This fluid was taken to the laboratory of Dr Hinkle Garst, who made only a smear. The gram-positive diplococcus was also seen here. Because of the negative smear and culture on the first tap, while we waited for confirmation of the gram-positive diplococci and in order not to lose any ground gained, 15 cc. of meningococcus serum was given intraspinally and 15 cc intravenously. That evening a cisternal puncture was made and 30 cc. of cloudy fluid was removed. The cell count was 2,800, smear and subsequent culture were negative.

March 9 there was decreased vomiting, the patient complained less of head pain and could bend the neck more easily. Cisternal puncture was made at 9 45 a m and 30 cc of fluid was removed, which was less cloudy and under less pressure, the cell count was 2,700. Cisternal puncture was made at 7 30 p m and 15 cc. of fluid was removed. The cell count was 2,800, the temperature varied from 99.6 to 102.4 F, smear and subsequent culture were negative.

March 10 at 10 45 a m 15 cc. of fluid was removed by cisternal puncture. The cell count was 2,500. The condition seemed to be improving. There was no vomiting, and a smear revealed many pus cells and occasional gram-positive diplococci, subsequent culture revealed gram positive diplococci. The fluid still showed on examination increased globulin and no sugar. At 6 p m a cisternal puncture was done, but after removal of almost 6 cc of bloody fluid the needle was withdrawn for fear of doing damage, as the child was so restless. The fluid was not sent to the laboratory.

March 11 at 9 15 a m 15 cc of fluid was removed by cisternal puncture, the cell count was 350, smear was negative and the temperature varied between 99.6 and 103 F. The mental condition was clear and the child was feeling much better.

March 12 at 10 a. m 22 cc. of fluid was removed by spinal puncture in order to determine the presence or absence of any block, the cell count was 250 the pressure was still diminishing and the fluid was much clearer. There was a slight increase of globulin and a faint trace of sugar. Fluid was cultured at 7 30 p m, a cisternal puncture was made and 24 cc. of fluid was removed. The cell count was 75.

March 13 at 9 a m 27 cc of fluid was removed by cisternal puncture, it showed that the fluid was still clearing up, the cell count was 60. It was decided to do cisternal punctures only once a day instead of twice a day from now on.

March 14 the mental condition was very good. Twenty-three cubic centimeters of fluid was removed at 9 a m by cisternal puncture. The cell count was 40, culture was made.

March 15 at 9 15 a m. 22 cc of fluid, which was becoming quite clear was removed by cisternal tap. The cell count was 38 and culture was negative after seventy-two hours.

March 16 at 9 30 a m. 15 cc of fluid was removed by cisternal puncture, the cell count was 20. The temperature was now between 99 and 100 F, a culture was taken.

March 17 at 1 p m 6 cc of fluid was removed by spinal tap by Dr C M Beavens. The cell count was 30 and culture was negative after seventy-two hours.

March 18 at 9 45 a m 30 cc of fluid was removed from the cistern. The fluid was clear and the cell count was 15. A culture was taken.

March 19 at 9 45 a m 15 cc. of fluid was removed by cisternal tap. The cell count was 21, and culture was negative after seventy-two hours. Globulin was normal and there was a trace of sugar.

March 20 at 9 30 a m 20 cc of fluid was removed by cisternal puncture, the cell count was 10 and the temperature normal.

March 21 at 9 a m 30 cc. of fluid was removed by cisternal puncture. The cell count was 10, culture was negative after seventy-two hours.

March 22 at 9 a m 15 cc of fluid was removed cisternally. The cell count was 12. In the face of four negative spinal fluid cultures, normal temperature and absent signs or symptoms of any sort, the child was discharged.

About ten days after leaving the hospital and returning home the child developed a lobar pneumonia, involving the right upper lobe. This was also followed by recovery.

COMMENT

It is not my purpose in this paper to criticize other treatments advised but merely to report another recovery and the therapy used. Such simple treatment as was used, being so successful, brought up the thought that pneumococcic meningitis, like pneumococcic pneumonia, might be self limited in its duration. In other words, if life can be continued by reducing pressure within the skull and giving supportive treatment, such as transfusions and fluids used will pneumococcic meningitis end of its own accord as will pneumonia caused by the same organism?

601 Fifth Street

PNEUMOCOCCIC CEREBROSPINAL MENINGITIS WITH RECOVERY

HOMER R SMITH M D MINNEAPOLIS

The report of this case of recovery from a pneumococcic cerebrospinal meningitis has been urged on me because it may be of some help to others and because it adds a little hope to a very desperate situation. The case was uncomplicated and the only etiologic factor was a mild so-called head cold about two weeks previous to the seeking of help.

Mrs. L., aged 43, first seen the morning of Aug 23, 1935 complained of an intense headache beginning two or three days before and gradually getting worse. In addition there was some pain in the neck, worse on the right side, and with considerable stiffness in attempted motion of any kind. The pulse was 88 and the temperature 101. The eyes reacted to light and in accommodation, and all the reflexes of the extremities were normal or nearly so. Nothing abnormal was heard in the lungs or heart sounds, although there was a history of a moderate cold about two weeks before. That evening the temperature rose to 104 and the leukocyte count taken then was 18,000. The next forenoon the patient was admitted to St Barnabas Hospital. All the symptoms regarding the head and neck were worse, the temperature was 103.8 F and the leukocyte count was 28,000. Urinalysis was negative.

A diagnosis of some kind of meningitis was made and a spinal puncture done for diagnosis. The spinal fluid came slowly in drops that were slightly bloody and cloudy. The laboratory examination of the fluid by Dr Floyd Grave revealed Nonne reaction, a heavy trace red blood cells numerous, white blood cells, 1,060 per cubic millimeter. Smears with the Gram stain showed a few gram-positive diplococci (pneumococci). A roentgen examination of the lungs by Dr R W Morse showed only a diffuse congestion.

It was thought that treatment with antipneumococcus serum should be attempted regardless of the report on the types present. The Felton serum, 20,000 units of types I and II combined was given intravenously the next day, August 25 repeated intramuscularly in one hour and again repeated intravenously in three hours from the first dose. The temperature, which was 105.8 by rectum August 25, dropped steadily each day, reaching normal August 31. On the same day it again began going up, reaching 104 at noon of September 2 with a leukocyte count of 30,000. The antipneumococcus serum was repeated intravenously and intramuscularly much the same as before, with a prompt drop of temperature to normal on the next day.

There were some minor fluctuations in temperature for the next three days but no more serum was used. The pulse and respiratory rates responded in their usual manner. During the

illness Dr G L Dovey reported all sinuses clear by transillumination. The patient left the hospital without complications September 17 and has continued an uneventful convalescence.

I regret that through some misadventure the pneumococci in the spinal fluid were not typed, therefore it must be presumed that they were in the groups acted on favorably by the antipneumococcus serum.

NONSPECIFIC PROTEIN THERAPY

A NUMBER OF FIRMS ARE ADVERTISING NONSPECIFIC PROTEIN PREPARATIONS UNDER PROPRIETARY AND SOMETIMES MEANINGLESS NAMES. RELATIVELY FEW OF THESE PREPARATIONS HAVE BEEN SUBMITTED TO THE COUNCIL ON PHARMACY AND CHEMISTRY AND NO PROPRIETARY NONSPECIFIC PROTEIN PREPARATION HAS BEEN ACCEPTED FOR INCLUSION IN NEW AND NONOFFICIAL REMEDIES. BELIEVING THAT PHYSICIANS DESIRE A MORE EXTENSIVE PRESENTATION OF INFORMATION CONCERNING NONSPECIFIC PROTEIN PREPARATIONS THE COUNCIL ON PHARMACY AND CHEMISTRY HAS AUTHORIZED PUBLICATION OF THE FOLLOWING REVIEW. IN ADOPTING THIS REPORT THE COUNCIL EXPRESSES APPRECIATION TO THE AUTHOR OF THE ARTICLE, DR RUSSELL L CECIL AND TO DR LUDVIG HEKTOEN WHOSE ARTICLE WAS PUBLISHED IN THE JOURNAL NOVEMBER 30.

PAUL NICHOLAS LEECH Secretary

RUSSELL L CECIL, M.D.

NEW YORK

Nonspecific protein therapy recently celebrated its twentieth anniversary. Like many other new forms of medical treatment, it has had its ups and downs, its defenders and detractors. If during the past few years it has lost some of its former popularity, one need not be surprised, for this has been the fate of most new methods of therapy. Furthermore, whatever prestige protein therapy has lost through the excessive enthusiasm of its supporters is being regained, at least in part, by reason of a better understanding of the fundamental nature of the reactions that follow its use.

In 1913 Fernando Torres,¹ a South American, reported successful results in the treatment of typhoid fever by giving typhoid vaccine intravenously and described the sharp reactions that followed its injection. Typhoid vaccine had been used previously to this in the treatment of typhoid, but the injections had always been given subcutaneously. In 1914 Dessy, Grapiolo and Fossati,² also Argentines, published a paper on the treatment of typhoid with typhoid vaccine. In this article the results obtained by subcutaneous injection were compared with those which followed intravenous injection. The authors concluded that the intravenous method gave much quicker results and described intravenous vaccine therapy in typhoid as a "brilliant" form of therapy. In 1914 Kraus and Mazza³ treated typhoid with intravenous injections of typhoid vaccine and noted that many cases so treated terminated abruptly by crisis or rapid lysis and that the mortality rate was definitely reduced. In the same year Ichikawa⁴ also reported favorably on this form of treatment. No doubt this method of vaccine treatment was originally intended as a form of specific therapy, but when Kraus and his co-workers⁵ later obtained similar results with colon

bacillus vaccine they opened the door to nonspecific therapy in all its various forms and modifications. Shortly after this, Lüdke⁶ showed that excellent results could be obtained in typhoid with intravenous injections of albumose, and Schmidt⁷ found that intramuscular injections of boiled milk would produce febrile reactions. Since then a large number of different agents, many of them proprietary, have been advocated, some for intravenous, others for intramuscular, use.

Miller and Lusk⁸ in 1916 were the first to use "fever therapy" in the United States, when they reported favorably on the intravenous use of typhoid vaccine in arthritis. About this time V C Vaughan⁹ was writing about poisonous proteins, maintaining that the keystone of the protein molecule was the "protein poison" and that fever was due to the parenteral destruction of proteins. Vaughan pointed out that the parenteral introduction of bacteria, pathogenic or nonpathogenic, living or dead, was followed by fever and that the fever was not the result of the growth of the bacteria but of bacterial destruction and splitting up of bacterial protein.

A distinction must be made between the terms "foreign protein therapy" and "nonspecific therapy." The latter is a broader term, including chemotherapy as well as protein therapy. In the present article, discussion will be limited to protein therapy.

PROTEINS USED

Many forms of protein and protein derivatives have been tried therapeutically. Among the more important may be mentioned:

- 1 Native proteins such as egg albumin, milk and casein.
- 2 Serums either human or animal.
 - (a) Normal serum
 - (b) Immune serums especially diphtheria antitoxin
- 3 Protein split products including peptone, proteose, albumose and histamine.
- 4 Enzymes and tissue extracts.
- 5 Bacterial vaccines.
- 6 Bacterial extracts (tuberculin, Coley's fluid and the like).

Malarial therapy is a form of foreign protein treatment. The protein is set free in the blood of the patient when segmentation of the malarial parasite occurs. The application of bee stings in various rheumatic conditions is probably another instance of protein therapy.

During the last few years a great many commercial protein products have been put on the market. Some of these are derived from milk, others from vegetable proteins, while still others are prepared from bacteria.

At the present time the three proteins most frequently used in America are typhoid vaccine, boiled milk and diphtheria antitoxin. A number of the commercial preparations also enjoy a considerable vogue. Stock and autogenous vaccines of various kinds are used extensively for therapeutic purposes, often no doubt with the intention of stimulating a specific rather than a nonspecific reaction, though there is little evidence to support the belief that a specific antigen-antibody mechanism is involved.

METHODS OF ADMINISTRATION

1 *Milk*—Ordinary skimmed milk, either fresh or pasteurized, is boiled for from five to ten minutes and then cooled to body temperature. The first dose for

adults is 5 cc injected intramuscularly, usually into the gluteal muscles. The dose is increased 2 or 3 cc with each injection until a maximum of from 10 to 15 cc is reached.

2 Diphtheria Antitoxin—As used for foreign protein therapy, diphtheria antitoxin is not given for its antitoxic property but because it is an available form of horse serum. The dose is not fixed but is usually from 2 to 4 cc, given intramuscularly. In doses of this size it will usually induce a temperature of from 100 to 101 F.

3 Vaccines—Ordinary stock and autogenous vaccines are given intramuscularly unless sharp thermal reactions are desired. When such is the case, typhoid vaccine is by far the most popular agent and is given intravenously. Ordinary typhoid vaccine is diluted with physiologic solution of sodium chloride to a point at which 1 cc contains 100 million organisms; the initial dose for adults is from 10 to 25 million. Gonococcus vaccine has also been used intravenously in the treatment of gonorrheal arthritis, and intravenous injections of streptococcus vaccine are now quite popular in the treatment of infectious arthritis.

I have observed that intravenous injections of gram-positive bacteria such as the streptococcus, pneumococcus and staphylococcus are much less likely to cause febrile reactions than the gram-negative organisms such as the gonococcus and typhoid bacillus. The reason for this difference is not clear.

THE NONSPECIFIC REACTION

The reaction to foreign protein injections varies from an almost imperceptible one to extreme shock associated with high fever, profound vasomotor disturbance and other constitutional phenomena. The reaction depends on the substance injected, the dose employed and the method of administration. It also depends a great deal on the physical condition of the patient and the number of previous injections.

Intramuscular injections of protein usually excite comparatively mild reactions. There may be only some local reaction at the point of injection and a constitutional reaction may be entirely absent. Sometimes a so-called focal reaction occurs, that is, a temporary flare-up of acute symptoms in some focus of infection, but this phenomenon is more frequently observed in the febrile reactions. When milk or some of the other proteins are injected intramuscularly in sufficiently large amounts, the local reaction may be supplemented by a mild chill and a rise of temperature of one or two degrees. With this rise in temperature there may be some increase in the leukocytes.

When foreign proteins are given intravenously, the reactions are sharper and make their appearance more promptly. When, for example, typhoid vaccine is given intravenously, the reaction usually occurs in from half an hour to one hour after the injection. At first there is marked chilliness or an actual rigor, with general aching similar to that observed at the onset of any acute infection. As the chill subsides, the temperature of the patient begins to rise. A maximum temperature of 103-105 F is obtained, usually within two to four hours after the injection. The increase in pulse rate that occurs is in proportion to the fever. Defervescence is usually rapid though it may be delayed in the first reaction.

In acute infections, such as typhoid or pneumonia, in which a temperature of 102 to 104 F already exists, the temperature during a protein reaction may sometimes go to 106 or 107 F. For this reason the dose of pro-

tein or vaccine should be very carefully gaged in the treatment of febrile conditions. As a rule, the dosage for febrile patients should be about half that for afebrile individuals.

One of the most interesting phases of the protein reaction is its effect on the leukocytes. Immediately following the injection there is a leukopenia due to the reduction of polymorphonuclear cells. With the onset of the chill a gradually increasing leukocytosis takes place, which reaches its maximum in about six hours and then gradually returns to the previous level. The leukocytosis is of the polymorphonuclear type. In afebrile patients the leukocytosis varies from 13,000 to 15,000 per cubic millimeter, but in acute infectious diseases, such as pneumonia, it may reach from 40,000 to 50,000.

The blood pressure shows a gradual rise during the chill. During the period of perspiration, however, the blood pressure gradually returns to normal.

The Focal Reaction—The focal reaction ("Herd-reaction" of the Germans) was first described in connection with tuberculosis, in which an injection of tuberculin was followed by exacerbation of symptoms in the original tuberculous focus. With the introduction of foreign protein therapy, focal reactions were noted by many observers. Menzer¹⁰ was the first to observe that tuberculous foci would respond with a typical focal reaction after the injection of streptococcus vaccine. Since this observation was made, numerous investigators have demonstrated the nonspecificity of focal reactions. Almost any inflammatory process, irrespective of etiology, will react to tuberculin as well as to a great variety of other agents. Even an old traumatic injury may be the site of a focal reaction following the intravenous injection of some foreign protein.

MECHANISM OF THE REACTION

The typical thermal reaction of protein fever can be divided roughly into three phases. Immediately after the intravenous injection there is a short prodromal period, which is characterized by first a stage of latency with no symptoms and later a stage of chill. Then the temperature begins to rise. The period from the onset of fever to the point of maximum temperature is referred to as the first, or "negative," phase. The second, or "positive," phase extends from the height of the fever to the return of normal temperature.

Space does not permit of a detailed description of the many physiologic changes that take place in the body during the protein reaction. Hench¹¹ lists them as follows: 1 Alterations in the basal metabolism. 2 Peripheral and splanchnic vasomotor changes, including alterations in blood pressure and in the caliber and permeability of the arterioles and capillaries. 3 Alterations in renal function, detectable in the output and in the acidity of the urine, excretion of phenolsulphonphthalein, and concentration of nitrogen, phosphate, urea, uric acid, allantoin and albumin. 4 Alterations in serum ferments, anti ferments, antibodies and the Wassermann reaction. 5 Alterations in organic activity demonstrated by increased secretion of lymph, bile, saliva, breast milk and menstrual flow and by changes in the activity of the liver, gastro-intestinal tract and spleen. 6 Alterations in the volume, specific gravity, freezing point and viscosity of the blood. 7 Alterations

¹⁰ Menzer, A. *Allgemeines und Besonderes über Vakzinetherapie*. Med. Klin. 8:311, 1912.

¹¹ Hench, P. S. *Usual and Unusual Reactions to Protein (Fever) Therapy*. Arch. Int. Med. 49:1 (Jan.) 1932.

in the cellular elements of the blood 8 Alterations in the fragility of the blood platelets and in fibrinogen, thrombokinase, coagulation time and sedimentation rate 9 Alterations in the chemical constituents of the blood, demonstrated by changes in the carbon dioxide tension of the plasma, carbon dioxide combining power, total nonprotein nitrogen of whole blood and of serum, sugar tolerance, albumin-globulin ratio and concentration of urea, uric acid, sugar, fat, total serum protein and chlorides

Just which one or more of these physiologic changes are responsible for the beneficial effects that often follow protein injections, it would be hazardous to say For example, Jobling and Peterson¹² attached great importance to the mobilization of enzymes, particularly proteases and ipases following the injection of proteins Modi¹³ in a recent article objects to the term "shock therapy," contending that injections of milk really act as a stimulus to the body Mueller¹⁴ maintains that in giving protein agents the same activities are affected which are naturally stimulated after bacteria have invaded the body in infections According to this writer the protein reaction involves a reaction of the entire vegetative nervous system which manifests itself in certain functional changes or organic activities, which are directed into two different channels, first, dilatation and increase of activity in the entire splanchnic area, and, second, contraction of the peripheral vessels and decrease in skin activities and in the functioning of the peripheral organs

While most writers stress the importance of fever in the protein reaction, Zimmer and Buschmann¹⁵ hold that acute conditions frequently require a fever reaction, while chronic conditions will often be best affected without any fever reaction Barr Du Bois and I¹⁶ have found that fever which followed intravenous injection of protease or typhoid vaccine is accompanied by increased heat production the amount of which corresponds to the degree of fever It was found that this increase in heat production followed van't Hoff's law, namely, that with a rise in temperature of 10 degrees C the velocity of chemical reactions increases between two and three times

Perhaps the most important function of the foreign protein reaction is the mobilization of immune bodies in the circulating blood For example, Bieling¹⁷ found that in rabbits immunized against typhoid bacilli there was an increased amount of typhoid agglutinins in the blood following the injection of colon, dysentery or diphtheria bacilli, and these observations have been corroborated by others Culver¹⁸ noted that in patients with gonorrheal arthritis the intravenous injections of proteases stimulated antibody formation just as actively as did gonococcus vaccine Wolff¹⁹ observed that in rabbits the bactericidal power of the blood could be

increased by both specific and nonspecific agents. Indeed, it has been shown by numerous authors that any form of fever is conducive to an increase of immune bodies in the circulating blood Whether this is due to increased formation or to increased mobilization of antibodies it is difficult to say It has been generally assumed that the beneficial effect of the foreign protein reaction is referable to the fever and that up to a certain point the higher the fever the better the results obtained There are some, however, who believe that the leukocytosis that accompanies the reaction has important therapeutic value

UNTOWARD REACTIONS

Severe and even fatal reactions sometimes follow the intravenous injection of foreign protein Such occurrences, however, usually take place in patients who are already seriously ill or who have been greatly overdosed with protein There have been surprisingly few severe anaphylactic reactions Among the complications attributed to foreign protein reactions have been delirium tremens, cardiac failure, vascular thromboses, acute nephritis, herpes labialis, rheumatic purpura, acute diarrhea, and activation of old pulmonary tuberculosis As pointed out by Hench,¹¹ there are certain reported sequelae of protein treatment, such as appendicitis, cholecystitis, glaucoma, colitis and respiratory infections, for which protein therapy has been deliberately used by the physician with impunity and at times with success Hench¹¹ has recently analyzed the reaction to typhoid vaccine, in most cases given intravenously, of 2,500 patients at the Mayo Clinic Unusual reactions were noted in only fourteen cases These were acute and sub-acute appendicitis, cholecystitis, enteritis, pleurisy, pericarditis, iritis, glaucoma, adenitis, vascular thrombosis and renal insufficiency In this large series, death occurred in only three cases, a mortality rate of 0.12 per cent

I have seen four fatal reactions from foreign protein therapy Three of these were in patients with lobar pneumonia who had received intravenous injections of pneumococcus aqueous extract (Huntton's pneumococcus antibody solution) In two of these cases death was apparently due to vasomotor collapse In the third case a sustained hyperpyrexia was followed by vasomotor collapse and death The fourth patient was in an advanced stage of dementia paralytica and after receiving typhoid vaccine intravenously developed a hyperpyrexia, which terminated in circulatory collapse and death I have never seen a dangerous reaction or any serious complications follow the intravenous use of typhoid vaccine in arthritic or in other patients suffering from some mild infection On the other hand, at the Mayo Clinic, untoward reactions have been noted more frequently in arthritic and vascular cases than in other conditions, though larger doses of protein have usually been employed in dermatologic and urologic cases than in the former groups

CLINICAL APPLICATION OF PROTEIN THERAPY

The literature on the clinical application of foreign protein therapy in various diseases is so enormous that in a short review of this kind reference can be made to only a limited number of them

Typhoid—Typhoid was the first infectious disease to be treated by foreign protein therapy Twenty years ago typhoid was still a fairly common disease and at that time a number of excellent studies appeared, report

ing the results obtained with protein therapy (Gay and Chickering,²⁰ McWilliams,²¹ Fairley,²² Wiltshire and MacGillcuddy²³ and others) Miller²⁴ states that the course of the disease is favorably influenced in 60 per cent of the cases. He adds, however, that intramuscular injections are safer than intravenous injections in this disease. Holler²⁵ used small doses of a 10 per cent solution of deuterio-albumose, beginning with two treatments a day and later giving one treatment daily, continuing the injections until the fever was broken. In 1917 he reported 350 cases treated by this method, with a death rate of only 0.5 per cent and an average duration of the disease of only ten days. So far as I can find, Holler's figures are the most impressive that have been reported in the literature.

Pneumonia—Pneumonia is a disease for which an efficacious serum therapy is available in more than 60 per cent of the cases. There still remains 40 per cent of pneumococcal pneumonias in which some other form of specific or nonspecific treatment would be feasible. In 1922 Larsen and I²⁶ reported a large series of cases of pneumonia in which Huntoon's antibody solution had been used intravenously in alternate cases. This controlled study offered an opportunity to observe the effect not only of specific but of nonspecific therapy as well, for the antibody solution contained immune bodies against only the three dominant types of pneumococci (types I, II and III). Therefore, when it was administered in the miscellaneous types it became a nonspecific form of therapy. Furthermore, it was nonspecific fever therapy, for each injection of antibody solution was usually followed by a chill and spurt in fever. A series of 110 group IV pneumonias thus treated gave a mortality rate of 16.4 per cent, while 121 untreated group IV cases showed a death rate of 24 per cent.

A similar opportunity occurred when Sutcliffe and I²⁷ reported on the effect of Felton's concentrated anti-pneumococcus serum in the treatment of pneumonia. The nonspecific effect of type I and type II serum could be studied in the miscellaneous group of pneumonias, this time without febrile reactions. Of 142 group IV patients who received type I-type II serum the death rate was 28.2 per cent. Of 133 group IV patients who received none, the death rate was 38.3 per cent.

Miller²⁸ treated fifteen cases of lobar pneumonia during the first two days of the disease with a single intravenous injection of typhoid vaccine. In six of the fifteen the pulse, temperature and respiration returned to normal a few hours after the reaction, but this improvement was temporary in three of the six. Three patients were permanently detoxicated and underwent rapid convalescence. Favorable results with typhoid

vaccine have also been reported by Cowie and Beaven²⁹ and by Wells.³⁰

It is obvious that in an infection of such comparatively short duration as pneumonia the interpretation of protein therapy would be difficult unless the injections were given very early in the disease. Furthermore, in spite of the statistical evidence in favor of protein fever therapy in pneumonia I feel that it is too drastic a form of treatment for routine use in such a severe infection as pneumonia. The fatal reactions mentioned earlier in this article support such a view.

Sepsis—The chills and temperature reactions of a patient with sepsis bear a strong resemblance to those which follow intravenous injections of foreign protein. A number of writers have reported favorable results from this method of treatment. For example, Wilmette³¹ reported a series of cases of puerperal sepsis with good results, some terminating by crisis. Ludke³² treated five cases with three rapid recoveries.

Syphilis—In the earlier days of protein therapy a number of investigators found it quite valuable in the treatment of the cutaneous manifestations of syphilis. With the development, however, of arsphenamine and heavy metal therapy, protein treatment has yielded to a more specific form of medication.

Protein therapy has maintained its prestige, however, in the treatment of dementia paralytica and to a less extent in tabes dorsalis. The outstanding advocate of foreign protein therapy in dementia paralytica has been Wagner-Jauregg.³³ The brilliant results obtained in this disease with typhoid vaccine and malarial therapy is indeed amazing when one considers how comparatively little benefit was gained from ordinary treatment of this condition with mercury and the iodides. As early as 1911, Pilcz³⁴ reported excellent results with tuberculin in the treatment of dementia paralytica. In 1917 malaria was first used therapeutically by Wagner-Jauregg,³⁵ who employed it in the treatment of dementia paralytica. This investigator had previously tried tuberculin and typhoid vaccine in the treatment of dementia paralytica and had obtained very good results following the febrile reactions produced by these agents. In 1928 his co-worker Gerstmann³⁶ summarized the results obtained with 2,000 patients in Wagner-Jauregg's clinic, and in 1931 Wagner-Jauregg³⁷ reported the results in 3,000 cases treated in the Vienna Psychiatric Clinic. The results reported by Wagner-Jauregg and by Gerstmann were most impressive and have been widely corroborated by other investigators in Germany, Great Britain and America. Wagner-Jauregg was convinced that malarial therapy was much superior to other agents for the production of thermal reactions, and this view is now quite widely held by neurologists. There are some, however, who believe that frequent injections of typhoid vaccine are just as efficacious, and certainly typhoid vac-

cine has practical advantages over malaria. Mackenzie,³⁸ for example, has obtained excellent results with typhoid vaccine and stresses the absence of the cachexia and anemia that so often follow malaria. Kunde, Hall and Gerty³⁹ are enthusiastic over typhoid vaccine therapy in dementia paralytica, and favorable reports have recently been published by Jennings⁴⁰ and by Young and Bennett.⁴¹

Both relapsing fever and rat-bite fever have been used therapeutically in dementia paralytica.⁴² The results with relapsing fever as reported by Plaut and Steiner⁴³ and more recently by Signorelli⁴⁴ seem to be about as good as those obtained by others with malaria, this is still further evidence that it is the febrile reaction and not the agent which produced the fever which is the essential part of the treatment.

The results of foreign protein therapy in tabes have not been so brilliant as those obtained in dementia paralytica, though Wagner-Jauregg reports that the lightning pains of gastric crises are often relieved by this treatment.

Other Nervous Diseases—In 1924 Grosz⁴⁵ reported very favorably on the treatment of multiple sclerosis with foreign protein therapy. Twenty-nine patients were treated with typhoid vaccine and forty-two with malaria. In both series something more than 25 per cent showed marked improvement. Other writers, notably Dreyfus and Hanau⁴⁶ and Schacherl,⁴⁷ have also reported good results in this disease. According to Dannhauser⁴⁸ and Leiner,⁴⁹ encephalitis and postencephalitic syndromes are favorably affected by protein therapy. Schmidt⁵⁰ recommends nonspecific therapy for dementia praecox, and Sutton⁵¹ has obtained remarkably good results in chorea with frequent intravenous injections of typhoid vaccine.

The unbiased reader cannot fail to be impressed by the enthusiasm of these writers. However, one should remember that the nervous diseases discussed are all characterized by alternating periods of improvement and relapse, so while one can expect striking improvement in many such cases after fever therapy, the possibility or even probability of a recurrence must always be borne in mind.

Acute and Chronic Arthritis—In the field of arthritis foreign protein therapy has achieved considerable success, and probably more articles have been written on the use of protein therapy in the treatment of various rheumatic conditions than on any other subject. Accord-

ing to Miller⁵² 50 per cent of patients with acute arthritis are free from discomfort after from two to three intravenous injections of typhoid vaccine, and in about 25 per cent of these the relief is permanent.

A number of years ago I⁵³ tried intravenous injection of typhoid vaccine on forty cases of acute arthritis, including a number of cases of rheumatic fever and gonococcal arthritis, and found that 32 per cent made a rapid and complete recovery without recourse to any other treatment, while of the remaining cases all but two showed improvement. The results in the seven cases of gonococcal arthritis were only fairly good. In my opinion foreign protein therapy should always be considered in the treatment of acute arthritis, especially for those cases in which salicylates have failed to give good results.

In chronic arthritis of the rheumatoid type, foreign protein therapy has not proved so satisfactory as in the acute form, though the immediate effects are sometimes quite striking. The swelling of the joints is diminished and the pain is decreased. In the majority of cases, however, relapse occurs sometimes in a few days, sometimes after several weeks or months of comparative freedom from pain. The literature on this subject is so extensive that only a few representative articles can be referred to. Laurie⁵⁴ obtained good results in rheumatoid arthritis by first giving a series of injections of colon bacillus vaccine intravenously in the hospital, then having the patient return once a week for additional injections. Lowenstein⁵⁵ gave intravenous injections of casein and found them helpful. Snyder and Ramirez⁵⁶ obtained "cures" in only six of their series of 70 cases, and these were all of less than two years' duration. Of the remaining cases, half showed definite improvement in the upper extremities, but in only one fourth was a similar relief obtained in the lower extremities. Miller,⁵² after a wide experience with typhoid vaccine in the treatment of chronic arthritis, states that, in the early stages of rheumatoid arthritis in which there is evidence of marked inflammation, fever therapy will occasionally give gratifying results, terminating the disease sometimes permanently, more frequently for a few months, after which it again becomes active but often yields to a second course of treatment. Campbell⁵⁷ treated seventy cases with typhoid vaccine and noted improvement in fifty-eight, though sixteen of these relapsed. In summing up he remarks "Protein shock is not and cannot be regarded as an ideal method of treatment, yet I am of the view that in the present state of our knowledge of rheumatoid arthritis, it offers greater possibility of success than any other treatment."

I have used typhoid vaccine with success in early cases of rheumatoid arthritis,⁵⁸ many such patients remain well. It is particularly useful in the febrile type of case. In chronic, well established cases I prefer small intravenous doses of streptococcus vaccine, too small to excite a febrile reaction. This is not a brilliant form of

therapy, but, if the injections are continued for several months, many patients make improvement under it. The injections are given every four or five days, in doses that range from 50,000 bacteria to a final dosage of perhaps fifty or a hundred million.

Diseases of the Skin—In dermatology, foreign protein therapy has been widely used, and with considerable success, in certain inflammatory conditions, such as furunculosis, carbuncle and other staphylococcal infections of the skin, and to a less extent in ringworm, lupus, pruritus and the like. Sometimes a persistent form of urticaria will yield promptly to boiled milk or to some form of bacterial vaccine. Especially good results have been claimed for colon bacillus vaccine in urticaria. Favorable results have been reported in psoriasis, but in my experience the benefit obtained in this disease has been very short lived. O'Leary⁵⁹ has found foreign protein most beneficial in the treatment of anthrax and erysipelas. Less favorable results were obtained in staphylococcal infections of the skin. He saw no benefit whatever from the use of nonspecific therapy in eczema or in allergic dermatitis. Schmidt⁶⁰ reports excellent results with milk therapy in erysipelas. For further data on protein treatment in dermatology the reader is referred to papers by Hall,⁶⁰ Weirauk⁶¹ and Low.⁶²

Diseases of the Eye—Nonspecific therapy in the form of boiled milk or typhoid vaccine has been employed extensively in iritis, uveitis, keratitis, conjunctivitis and other inflammatory conditions of the eye. There seems to be some disagreement as to the benefit to be derived from protein therapy in trachoma. Friedlander⁶³ and Howard⁶⁴ both report good results in this condition, but other writers, such as Steindorff,⁶⁵ are not so enthusiastic. Miller²⁴ states that there is no acute infection in which the results of foreign protein therapy are so good as in acute iritis. According to this writer the results are immediate and the relief permanent, and this opinion is corroborated from many sources. Key⁶⁶ produced experimental ulcers on the cornea of rabbits and obtained prompt relief with diphtheria antitoxin.

Scarlett⁶⁷ found horse serum just as satisfactory as diphtheria antitoxin. He considers protein therapy a "valuable adjunct" in the treatment of ocular infections, but always in conjunction with regular routine treatment. A. C. Woods⁶⁸ believes nonspecific protein therapy one of the most valuable of weapons in certain ophthalmologic conditions but warns that it is "specialized therapy" and that age, duration of disease and condition of the patient must all be considered in every case. Benedict⁶⁹ found that, in eye work, shifting from one form of protein therapy to another often proved to be more effective than continuing with the

same form. If space permitted, many other enthusiastic reports could be cited, such as those of Allen,⁷⁰ Verhoeff⁷¹ and Gaston.⁷²

Gynecology—In pelvic disease the most important field of protein therapy has been in adnexal infections of an acute or subacute type. In such conditions the results of protein therapy have often been quite striking. The consensus seems to be, however, that its chief function is in the relief of pain and extreme tenderness. There is considerable doubt as to just how often a tubal infection is "cured" by protein therapy. Gellhorn⁷³ is enthusiastic over injections of milk for such infections, particularly gonorrheal infection of the tubes and Bartholin's glands. Chaudano⁷⁴ employed milk, but he is not so enthusiastic, nor is Kauert,⁷⁵ who employed "aolan," a milk derivative. Other writers, however, notably Rawls,⁷⁶ Mohler,⁷⁷ Llewellyn,⁷⁸ Jarcho,⁷⁹ Champlin⁸⁰ and Hibbert,⁸¹ used either milk or aolan with excellent effect.

L. H. Stuhler⁸² of the Mayo Clinic has found foreign protein therapy a good measure in pelvic cellulitis and in acute as well as chronic salpingitis. In his experience it is especially adapted to those early cases in which pus formation has not yet started. He considers protein therapy of value even in the well advanced cases, and in his opinion it is the method of choice in cases in which surgery is not yet indicated or is contraindicated. Stuhler believes that protein therapy has saved a great many patients from major surgical operations. This writer goes so far as to say that if he were limited to one method of treatment in salpingitis he would choose foreign protein therapy without hesitation.

Genito-Urinary Infections—Gonorrhea and its complications have been treated by various forms of nonspecific therapy as well as by gonococcus vaccine. Particularly good results have been reported in epididymitis and in gonococcal arthritis. Antoni⁸³ and Müller⁸⁴ have noted remarkable results from milk therapy in buboes.

For gonococcal infections, however, fever therapy is now more successfully used in the form of diathermy or the "short wave" than by typhoid or gonococcus vaccine. The subject of fever therapy in gonococcal infections is well reviewed in a recent article by Desjardins, Stuhler and Popp.⁸⁵

Peptic Ulcer—One would hardly expect protein therapy to have any value in the treatment of peptic

ulcer Pribram,⁸⁶ however, has reported a large series of ulcers treated by intravenous injections of a vegetable albumin (novoprotein) and states that the pain was much relieved in from 50 to 60 per cent of the cases. He even goes so far as to assert that roentgen observations indicate healing of the ulcer. Treatments were given at intervals of from two to four days, the patient receiving a total of eight or ten injections. Martin,⁸⁷ Mueller,⁸⁸ Miller²⁴ and others have confirmed Pribram's results, at least so far as relief of gastric pain is concerned. Miller found that immediate effect of typhoid vaccine on ulcers was very good and stresses the alleviation of pain. A certain number of his cases, however, relapsed shortly after the treatment. In view of the marked tendency of ulcers to periodic remissions and exacerbations, the results of protein therapy in such conditions must be accepted with considerable reservation.

Vascular Disease—One of the newer fields for foreign protein therapy is that of vascular disease, particularly thrombo-angitis obliterans. In vascular disease, however, it is probably the vasodilatation rather than the fever, leukocytosis or mobilization of immune bodies that is responsible for the beneficial effect obtained. According to Wright,⁸⁹ the desired physiologic effect of fever therapy in vascular disease is release of spasm of the partially occluded vessels with resulting increase in the local capillary circulation. This is followed by cessation of pain and healing of ulcerations, if they exist.

The pain in thrombo-angitis obliterans is often excruciating, and Brown⁹⁰ considers the intravenous administration of typhoid vaccine the best medical measure for its relief. Allen and Smithwick⁹¹ have reported successful results with typhoid vaccine in Buerger's disease, in the gangrene of arteriosclerosis, and in purely vasomotor types of vascular occlusion. These authors used doses of from 125 to 300 million bacilli, but Wright believes that the chill should be avoided and recommends small doses, just enough to produce 2 or 3 degrees of fever. Wright recommends an initial dose of 10 million typhoid bacilli, with an increase of 10 million with each subsequent injection.

Goodman and Gottesman⁹² have also reported enthusiastically on the use of fever therapy in vascular disease, particularly Raynaud's disease. They say "Our most satisfactory results were obtained in the three cases of Raynaud's disease that we treated with foreign protein. Immediate and lasting improvement resulted in each case. No other treatment was employed."

It would appear from this brief survey that protein therapy has found one of its most important uses in vascular disease. The danger of thrombosis as a complication of the treatment must be kept in mind. It is for this reason that Wright warns against inducing chills in these patients and advises small doses of protein that will produce fever without the preceding rigor. Barker⁹³

of the Mayo Clinic has recently reported favorable results in peripheral vascular disease with typhoid H antigen. This antigen is a derivative of the typhoid bacillus and when injected intravenously produces fever but definitely less chill than the ordinary typhoid vaccine. In view of the absence or diminution of the chill, Barker believes that it is a better product for vascular disease than the usual typhoid vaccine.

Allergic Diseases—In 1909 Biedl and Kraus⁹⁴ found that an animal sensitized to a foreign protein could be partially desensitized with peptone, and this work has been confirmed by other investigators. No doubt this explains the beneficial effects sometimes obtained by protein therapy in such conditions as asthma, hay fever and urticaria. Rackemann⁹⁵ has pointed out that bacterial vaccines in asthma are beneficial in proportion to their power to produce a local reaction at the site of injection. I once saw an accidental local infection in the arm of an asthmatic patient at the site of a vaccine injection. The improvement that ensued from this local infection was much more marked than that which the patient received from any subsequent vaccine injections. Van Leeuwen⁹⁶ has used tuberculin in the treatment of asthma and reports 300 cases treated by this method with 50 per cent completely or almost completely cured and from 25 to 30 per cent improved.

As Miller²⁴ remarks, however, it is difficult to explain the permanent cures reported by various writers on asthma, for it is generally recognized that desensitization is a more or less temporary state.

CONTRAINDICATIONS

The more important contraindications to intravenous foreign protein therapy are

1 Advanced arterial, renal or cardiac disease. Patients with cardiac decompensation should not have intravenous protein therapy. On the other hand, rheumatic endocarditis with good compensation is not a contraindication.

2 Allergic states or conditions of marked protein sensitivity, such as angioneurotic edema, giant urticaria and the like.

3 States of extreme exhaustion following prolonged illness.

4 Pulmonary tuberculosis, active or quiescent.

5 Hemorrhagic conditions, such as hemophilia, bleeding ulcers and the like.

6 Chronic alcoholism, for fear of delirium tremens.

7 Marked nervous sensibility, such as that seen in hyperthyroidism and the like.

The contraindications for subcutaneous or intramuscular injections of protein are much less stringent than for the intravenous injections. Indeed, there are very few patients who cannot take with impunity small doses of bacterial vaccine, boiled milk or serum subcutaneously.

There has been considerable difference of opinion concerning the danger of protein therapy in patients with pulmonary tuberculosis. A number of writers have reported pulmonary focal reactions in tuberculous patients after injections of protein. Hektoen and Irons⁹⁷ cite five cases of latent pulmonary tuberculosis activated by the use of stock vaccines. I recall one case

of spondylitis in a young man who was treated in the New York Hospital with typhoid vaccine intravenously and who developed active pulmonary tuberculosis a short time after leaving the hospital. On the other hand, Brown, Heise, Petroff and Wilson⁹⁸ noted focal activation in only two of 124 tuberculous patients who received typhoid vaccine subcutaneously for prophylactic purposes.

COMMENT

One of the most difficult problems in modern medicine is the proper evaluation of new therapeutic measures that cannot be tested accurately either by animal experimentation or by carefully controlled statistical studies on patients but which rest for their acceptance entirely on an empirical basis. Foreign protein therapy is an excellent example of such a form of treatment. Animals have been used for studying the physiologic effect of proteins, but with the exception of Key's studies on experimental iritis in rabbits there has been very little effort to test the value of foreign protein experimentally. Numerous statistical studies on foreign protein therapy have been reported, but most of them have been uncontrolled—an omission that perhaps is pardonable in the study of chronic infections, in which controls are always difficult of interpretation.

Whatever popularity foreign protein therapy has received rests largely on an empirical basis. The earliest reports were clinical studies on patients. Experimental work came later. These facts, however, should not raise prejudice against protein treatment, provided the clinical reports can be relied on. Physicians have always been compelled by force of necessity to make use of empirical remedies in the treatment of disease and will probably continue to do so for many years to come.

What then should be the place of foreign protein therapy in modern practice? This question can be answered readily enough with respect to subcutaneous and intramuscular injections of vaccines or proteins such as milk, peptone and the like, which produce little or no reaction in the patient when given in reasonable doses. As a rule these injections do no harm, but often they fail to do any good. The benefit to be derived from protein therapy often seems to be in proportion to the amount of constitutional reaction and fever produced. Such being the case, the physician will in many cases be tempted to resort to intravenous protein therapy with some fever-producing substance like typhoid vaccine, and what every practitioner would like to know is just when he is justified in using this rather drastic form of treatment. He has in mind the question once propounded by Theobald Smith: How much energy does a reaction of this sort cost the patient, and is the final result worth the cost?

I am disposed to agree with Miller⁹⁴ that typhoid vaccine, when given in proper doses and to carefully selected patients, is not a dangerous form of therapy. In the case of intravenous therapy, the most important precautions are to (1) make the first dose a small one and (2) not to try protein therapy on patients who are in an extreme state of exhaustion. The indications and contraindications for this method of treatment have already been discussed. Experience with any form of therapy is a valuable asset to the practitioner, especially when an element of risk enters into its application.

Protein therapy falls into this category, but any well trained physician should be qualified to practice it, provided he will take the necessary precautions. I much prefer to administer fever therapy in a hospital. It can be undertaken in the patient's home if a nurse is in attendance, but the hospital is much to be preferred. Under no conditions should fever therapy be undertaken in the doctor's office. There is too much danger of a chill on the way home.

I believe that foreign protein therapy will always find its greatest usefulness in acute and subacute infections. The glowing reports by some writers on the achievements of protein therapy in various chronic diseases have not been widely corroborated. It is significant that many of these rather startling claims have been made with regard to certain chronic infections such as peptic ulcer, multiple sclerosis and chronic arthritis, which are characterized by periodic remissions and exacerbations.

A great many proprietary remedies have been offered to the medical profession as substitutes for milk, serum and ordinary bacterial vaccines. In many cases special claims have been made for these products, in language that is often mystifying, to say the least. As an example, I quote the following from an editorial in *THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION*⁹⁹ concerning the claims made for "Proto-Enzyme for the Involvements in Gonorrhea": "The nonspecific proteins contained are claimed to stimulate the production of phagocytes which 'attack and ingest the starved gonococci, changing them into peptones and releasing these peptones osmotically into the blood stream,' where they are taken up by red blood corpuscles.

carried to the liver, where they are split by the hepatic hormones into fatty acids and urates, and easily eliminated by the emunctories.'" It is doubtful whether the man who wrote these words knew what they meant, certainly they mean nothing to a physician who knows his physiology. Furthermore, it is extremely unlikely that these commercial products possess any virtues which are not equally inherent in typhoid vaccine, or the other agents commonly employed for nonspecific therapy.

Finally, as remarked by Hench,¹⁰⁰ foreign protein therapy may prove to be more "specific" than "nonspecific." Foreign protein produces a great many different kinds of specific reactions in the body. It is already being found that some of these reactions are helpful in one disease, while others are helpful in another. For example, in the treatment of peptic ulcer the specific effect desired is to keep the gastric acidity low. In dementia paralytica the fever is presumed to be the desirable part of the reaction. In vascular disease we are concerned exclusively with the degree of vasomotor dilatation produced. In certain other infections it may be the leukocytosis or the mobilization of the specific immune bodies that produces the beneficial result. The future study of foreign protein therapy will no doubt bring to light many new facts which will eventually take this procedure out of the realm of "nonspecific" into that of "specific" treatment, and it is quite possible that, while for the moment foreign protein therapy may seem to have lost some of its prestige and popularity, we may be on the verge of information that will result in a renewed and more skilful application of this method in the treatment of disease.

100 Hench P S. Personal communication to the author.

CONCLUSION

It may be said that protein therapy, after twenty years of investigation and clinical trial, rests on a sound foundation and has now achieved a permanent though limited place for itself in modern therapeutics. In the realm of infectious diseases it has met with general acceptance in the treatment of (1) infections of the eye, (2) acute and subacute pelvic infections, (3) certain infections of the skin, (4) a few generalized infections, such as sepsis and typhoid, (5) acute and chronic forms of infectious arthritis, and (6) cerebrospinal syphilis, especially dementia paralytica.

In the field of vascular disease, notably in thrombo-angitis obliterans, foreign protein therapy also appears to have earned a secure therapeutic position.

AMERICAN MEDICAL ASSOCIATION

(See Index page 1915)

A plan for the survey of tuberculosis hospitals and sanatoriums in the United States was adopted by the Council on Medical Education and Hospitals in October 1932 and was authorized by the House of Delegates of the American Medical Association at its session the following year. This was no new venture but was in conformity with a well defined program of hospital service. To collect and disseminate information about hospitals is one of the functions of the Council which is not limited to any particular field.

The plan of survey was, in a large part, developed and its execution directed by Fritz H. Arestad, M.D., a member of the Council's staff of hospital examiners, who also made a majority of the visits to these hospitals and supervised the preparation of the statistics.

In undertaking this survey, the Council recognized that the medical profession at large is concerned with the problem of tuberculosis control and therefore interested in obtaining a better knowledge of the tuberculosis field. The problem of tuberculosis is not limited to specialists but is one in which the average physician has a share not only from the point of view of diagnosis and treatment but also from the broader aspect of public health. Likewise, tuberculosis hospitalization is no longer the exclusive function of the sanatorium field but has extended into the general hospitals and into other institutions of special service

PURPOSE OF SURVEY

The purpose of the survey was not to standardize the tuberculosis hospitals but rather to (1) appraise institutions for the American Medical Association's Hospital Register, (2) evaluate educational facilities for the training of resident physicians, (3) collect factual data about all tuberculosis institutions in the United States, and (4) present to the medical profession a report of the hospital facilities now available in the United States for the treatment of tuberculosis. An opportunity was afforded to study the educational facilities available for the training of medical students, interns, resident physicians and other graduate physicians. The Council has approved a number of tuberculosis hospitals and sanatoriums for the training of resident physicians and has extended its approval to postgraduate courses in a few of the most important institutions.

METHOD OF SURVEY

The plan of the survey differed little from the methods employed by the Council in its dealings with the medical schools and with other hospitals. As in the past, reliance was placed on personal inspections followed by a supplementary questionnaire. Although the investigation represented a concentrated study of a particular hospital field, it was conveniently combined with the routine inspections of other hospitals. The work was carried out by the Council's regular staff of hospital examiners and required two years for completion. During that time, visits of inspection were

made to all sanatoriums, preventoriums and the principal tuberculosis departments of other hospitals. All together, 656 institutions were inspected exclusive of tuberculosis departments in nervous and mental hospitals that had been surveyed during 1931 and 1932.

Throughout the investigation, an outlined plan was followed to insure uniformity of information and reports. The personal inspections were concerned with the following features: (1) physical plant, including location, ownership and control, finances, general utilities, food service, and bed capacity, (2) special medical facilities, such as x-ray, laboratory, necropsy facilities, pneumothorax equipment, facilities for minor, major and chest surgery, dental equipment, pharmacy, and heliotherapy, (3) staff and personnel, with reference to the regular medical staff, attending and consulting physicians, dental staff, and nursing, technical and general personnel, (4) medical service, including admission procedure, diagnostic service, general treatment and special therapeutic procedures in the form of pneumothorax, phrenic nerve operations, thoracoplasties, and so on, (5) records—administrative, clinical and statistical, and (6) special features, such as educational activities, research, medical library, community service, recreational facilities, occupational therapy and rehabilitation.

Since the investigation took two years, it was to be expected that changes would occur in some of the institutions that were included in the first part of the survey. In order to record such changes and to supplement the information obtained by inspection, a questionnaire was prepared which in itself was a comprehensive report containing 208 separate items. The form was designed with the assistance of the officials of the American Sanatorium Association and the National Tuberculosis Association, whose continued loyal support contributed largely to the success of the survey. Subsequently, many sanatorium superintendents offered valuable suggestions, so that the questionnaire in its final form represented not only the opinion of the Council but also the knowledge and experience of those who are more closely connected with the tuberculosis field.

SCOPE OF SURVEY

Questionnaires were sent to 471 sanatoriums and to 133 of the principal tuberculosis departments. Not only were returns received from 98.9 per cent of the sanatoriums and 92.5 per cent of the tuberculosis departments, but the forms were filled out with unusual accuracy and completeness. Reports were obtained also from fourteen preventoriums and from approximately 5,600 other hospitals which had been requested to report the number of beds available for the treatment of tuberculosis, the number of tuberculous patients admitted last year, and the number of tuberculous patients now under treatment.

The data obtained by inspections and by hospital reports were later supplemented by information supplied by state departments of health and state anti-

tuberculosis associations. By this means the Council was able to obtain a more complete picture of the local tuberculosis problems as well as a clearer understanding of the various methods of tuberculosis control.

The report that follows, therefore, covers 471 sanatoriums, 740 tuberculosis departments and twenty-nine

A classification on the basis of control shows 169 federal institutions offering facilities for the treatment of tuberculosis, 284 state institutions, 250 operated by counties, eighty by municipalities, twenty-four conducted jointly under city and county control, and 433 institutions under private management. preventoriums, a total of 1,240 institutions. It is based on (1) the inspection of 656 tuberculosis institutions, (2) data obtained from 602 tuberculosis questionnaires, (3) reports from 5,600 other hospitals, and (4) information supplied by state health departments and state antituberculosis associations.

METHOD OF CLASSIFICATION OF TUBERCULOSIS INSTITUTIONS

For the purpose of this report the institutions can first of all be separated into three groups: the sanatoriums, the tuberculosis departments of other hospitals, and the preventoriums. The term "sanatorium" has been limited to institutions operated exclusively for tuberculosis, "tuberculosis department" signifies a tuberculosis service in conjunction with any other hospital activity, and the term "preventorium" is applied to children's units operated independently and on a permanent basis. Consequently, the list of preventoriums will not show preventorium units conducted as part of a sanatorium and will not include summer camps for children.

lists the tuberculosis institutions by states and according to control, shows the sanatoriums, departments and preventoriums classified as follows:

Classification by Control

| | Sanatoriums | Departments | Preventoriums | Total |
|-------------|-------------|-------------|---------------|-------|
| Federal | 18 | 151 | | 169 |
| State | 65 | 210 | | 284 |
| County | 173 | 71 | 6 | 250 |
| City | 22 | 53 | | 75 |
| City county | 10 | 7 | 2 | 19 |
| Private | 178 | 234 | 21 | 433 |
| Totals | 471 | 740 | 29 | 1,240 |

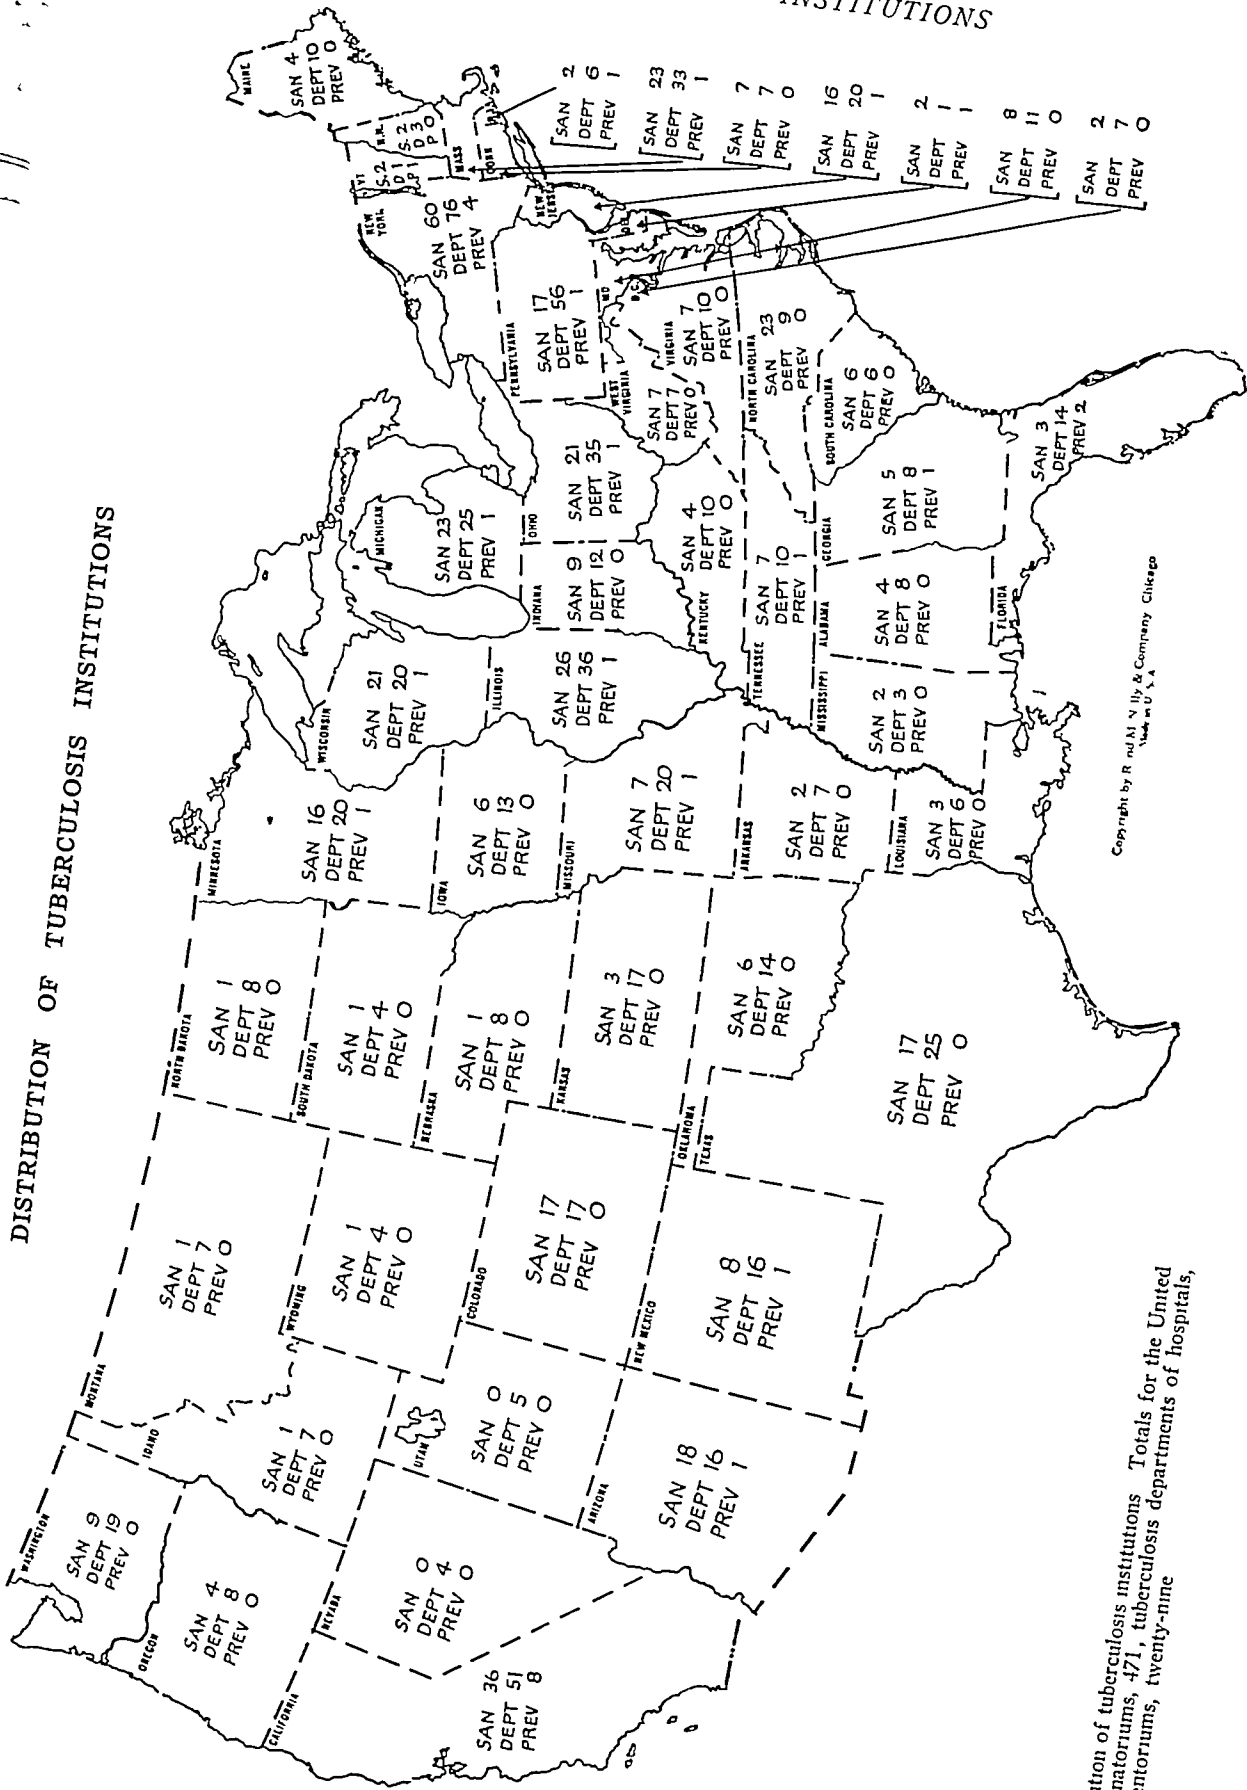

NUMBER, SIZE AND DISTRIBUTION OF TUBERCULOSIS INSTITUTIONS

There are 471 sanatoriums for the treatment of tuberculosis. Reference to the foregoing tabulation will show that eighteen are federal, sixty-five state owned, 173 county, twenty-two city, fifteen city and county, and 178 privately controlled. According to table 2, which shows the tuberculosis institutions by

TUBERCULOSIS INSTITUTIONS

1857

DISTRIBUTION OF TUBERCULOSIS INSTITUTIONS

Distribution of tuberculosis institutions Totals for the United States sanatoriums, 471, tuberculosis departments of hospitals, 740, preventoriums, twenty-nine

Copyright by R. and M. V. Ily & Company Chicago
New U.S.A.

states and by size, there are 41 sanatoriums of less than 25 beds, 90 of 25 to 49 beds, 132 of 50 to 99 beds, and 208 which have a capacity of 100 beds or over

The distribution of the sanatoriums as shown in the map and in table 1 corresponds closely to the density of population except in a few states where climatic conditions have influenced the development of sanatorium facilities beyond local needs. There are eight states with more than twenty sanatoriums each, six

floors or porches, and in 211 the degree of segregation was not reported

The variation in size of the tuberculosis departments is of some significance. In general, the larger departments may be considered part of the regular sanatorium service in a community, whereas the great number of small departments can be taken as an indication of the extent to which tuberculosis hospitalization has been developed in the general hospital field. Eighty depart

have from ten to twenty, thirty-three states have less than ten, and two have no sanatorium facilities

The tuberculosis departments, which number 740 in all, are also shown in table 1. Of these, 151 are federal, 219 state, seventy-one county, fifty-eight city, seven city and county, and 234 under private control. An analysis of the reports shows that 418 tuberculosis departments are connected with general hospitals, twenty-six with isolation hospitals, 193 with nervous and mental institutions, twenty-one with orthopedic hospitals, seventeen are connected with other hospitals, and sixty-five are departments of institutions, including sixteen homes for the aged and forty-eight reformatories and prisons

The extent to which isolation facilities have been provided for tuberculosis in general and other hospitals is illustrated by the table in the adjoining column, which shows that 225 tuberculosis departments are housed in separate buildings, 304 occupy separate wings, wards,

ments are of 100 beds or over, eighty-two have a capacity of from fifty to ninety-nine beds, ninety-four have from twenty-five to forty-nine beds, and 484 have

Isolation Facilities for Tuberculosis

less than twenty-five beds. The second column in table 2 showing tuberculosis departments of less than twenty-five beds includes 266 that did not report the number of beds set aside for tuberculosis

All states have hospitals with tuberculosis departments, as shown in table 1. Eight have more than twenty each, eighteen have from ten to twenty, sixteen have from five to nine, and in seven states there are less than five tuberculosis departments.

There are twenty-nine preventoriums that are operated as independent institutions. Twenty-one are privately owned, six are county institutions, and two are operated jointly under city and county control. The

men, 25,716 for women, 11,647 for children, and 22,284 unassigned. Four hundred and seventy-one sanatoriums operated exclusively for tuberculosis have 64,997 beds, the 740 tuberculosis departments have 28,534 beds, and the twenty-nine preventoriums reported 1,667 beds.

There are 14,468 tuberculosis beds in general hospitals, 9,478 in nervous and mental institutions, 2,556 in tuberculosis and isolation hospitals, 1,322 in depart-

capacity varies from ten to 247 beds. Nine institutions have less than twenty-five beds, seven from twenty-five to forty-nine beds, nine from fifty to ninety-nine beds, and in four the capacity is 100 beds or over. There are eight preventoriums listed in California, four in New York, two in Florida, one in each of fifteen states, and none in thirty-one.

The foregoing figures do not represent all the facilities for children, however, for there are more than 250 sanatoriums and tuberculosis departments that admit children for sanatorium or preventorium care. These facilities are included in the sanatorium classification and are described under "Hospitalization of Children."

BED CAPACITY

Reports from 1,240 institutions indicate that there are at present 95,198 beds available in the United States for the treatment of tuberculosis, 35,551 for

men, 25,716 for women, 11,647 for children, and 22,284 unassigned. Four hundred and seventy-one sanatoriums operated exclusively for tuberculosis have 64,997 beds, the 740 tuberculosis departments have 28,534 beds, and the twenty-nine preventoriums reported 1,667 beds.

The number of available beds for Negroes cannot be stated definitely. However, 104 institutions report 3,751 beds for colored patients, and 171 additional hospitals state that beds are made available for Negroes in accordance with demands for hospitalization.

New construction for tuberculosis may add 6,661 beds. Private institutions report plans for 487 new beds, and the state and local public institutions indicate that new construction may increase their capacity by 6,124 beds.

New York State has the greatest number of beds for tuberculosis, 14,582, California is next with 7,389, Pennsylvania has 6,293, Illinois 5,404, Massachusetts 5,350, Michigan 4,991, Ohio 4,670 and New Jersey 3,595 beds. Six states have between 2,000 and 3,000 beds, twelve states have from 1,000 to 2,000 beds each, ten states have from 500 to 1,000 beds, and thirteen states have less than 500, including Nevada, Utah and Wyoming, which do not exceed 100 beds.

In table 3 the bed capacity of tuberculosis institutions has been classified by states. Table 4, which represents

private hospitals. The six county preventoriums have 364 beds, two under city and county control have 130, and twenty-one privately owned preventoriums have 1,173 beds.

PATIENT POPULATION

To illustrate the extent of tuberculosis hospitalization in the United States it becomes necessary to show by figures the changes that occur annually in the patient population of tuberculosis institutions. The statistical data used for this purpose are based on reports received during 1934.

Table 4—Bed Capacity of Tuberculosis Institutions by Control and by States

| State | Federal | | State | | County | | | City | | City County | | | Private | | | Number of Beds | | | Total Beds in Institutions |

capacity by control and by states, shows that there are 10,940 beds in federal hospitals, 66,592 in other public institutions, and 17,666 beds for tuberculosis in privately owned sanatoriums, hospitals and preventoriums. There are 4,103 beds in the federal sanatoriums and 6,837 in departments of federal hospitals. In the remaining group of public institutions the state sanatoriums have 17,308 beds, the county sanatoriums 20,114, those operated by municipalities 7,365, and the city and county sanatoriums 2,423. Departments of hospitals under state control have 9,792 beds for tuberculosis, county departments have 3,551, departments of city hospitals have 4,530, and hospital departments of city and county institutions have 1,015 beds. In the private sanatoriums there are 13,684 beds, and 2,809 beds are available for tuberculosis in departments of

1 *Admissions*—Reports from 458 sanatoriums, 607 tuberculosis departments and twenty-four preventoriums, representing 89,173 beds, or 93.7 per cent of the total capacity, indicate that there were 121,706 patients admitted during a twelve months period. Of this number 44,243 were men, 28,434 women, 15,523 children and 33,506 not classified. These figures include readmissions, which, according to a survey made by the National Tuberculosis Association in 1931 amount to nearly 7 per cent of the patients admitted. There are no data available to show the number of patients admitted by transfer from other tuberculosis institutions.

The sanatoriums admitted 70,601 patients, 27,520 men, 21,601 women, 10,394 children and 11,086 not designated. Of these patients, 5,078 were admitted in

the federal sanatoriums, 51,043 in the other public sanatoriums, and 14,480 in those under private control. Seven sanatoriums operated by fraternal organizations admitted 445 patients, twenty-three under church management had 3,196 admissions, and the remaining private sanatoriums admitted 10,839.

There were 47,007 admissions in the tuberculosis departments: 16,723 men, 6,833 women, 1,031 children and 22,420 not designated. Departments under federal control admitted 10,445 patients, those under private management had 6,839 admissions, and all others

In New York State there were 24,331 admissions reported, 10,093 in California, 9,133 in Pennsylvania, 6,430 in Illinois, 5,914 in Michigan and 5,908 in Ohio. Five states have less than 200 admissions annually, namely, Delaware, Nevada, New Hampshire, Utah and Wyoming. Total admissions by states are shown in table 5.

2 Patients Treated—On the basis of reports from 559 tuberculosis institutions, representing 78,128 beds, or 82 per cent of the total capacity, there were 166,818 patients treated: 61,861 men, 40,938 women, 20,934

Table 5—Number of Patients Admitted in Tuberculosis Institutions During Twelve Months Period
(According to Reports Received During 1934)

received 29,723 patients. A classification by type of service shows that 37,124 tuberculosis patients were admitted to general hospitals, 2,425 to tuberculosis services in nervous and mental institutions, 1,800 in departments of institutions, prisons and reformatories, 574 to orthopedic hospitals, 4,456 to institutions having combined tuberculosis and isolation services, and 628 patients to other types of hospitals.

Twenty-four preventoriums admitted 4,098 patients. This number does not include the children admitted to preventorium services in sanatoriums and tuberculosis departments. Five county preventoriums admitted 471 children, those under city and county control had 63 admissions, and seventeen private preventoriums admitted 3,564.

children and 43,085 not classified. According to table 6 there were 121,962 patients treated in the tuberculosis sanatoriums, 40,327 in tuberculosis departments, and 4,529 in the independently operated preventoriums. The sanatoriums treated 43,700 men, 34,736 women, 14,982 children and 28,544 unclassified patients, while 18,161 men, 6,202 women, 1,423 children and 14,541 patients not designated were treated in the tuberculosis departments of other hospitals.

3 Patients Discharged—Table 7 shows 432 sanatoriums, 112 tuberculosis departments and eleven preventoriums which reported on the number of patients discharged during a twelve months period. All together, 555 institutions and 78,160 beds are represented: 82 per cent of the total capacity. The discharges includ-

ing deaths total 97,381 39,754 men, 25,320 women, 12,113 children and 20,194 not classified The sanatoriums, representing 63,228 beds, discharged 66,423 patients, including 25,054 men, 19,769 women, 9,718 children and 11,882 not designated The tuberculosis departments show a more rapid turnover There were 29,502 patients discharged in 112 departments representing 14,191 beds An analysis shows that 14,700 were men, 5,551 women, 939 children and 8,312 not classified Incomplete reports from the preventorium group show 1,456 children discharged

the far advanced terminal cases should be under institutional care

4 *Average Daily Census of Patients*—Five hundred and ninety-two tuberculosis institutions representing 83.8 per cent of the total bed capacity maintained an average daily census of 69,024 patients during the twelve months period covered by this report In the sanatorium group, 460 institutions with a capacity of 64,829 beds had a daily average of 56,325 patients Of the tuberculosis departments, 111 with a capacity of 13,748 beds reported an average daily census of 11,648,

The deaths numbered 16,229, of which 10,923 occurred in the sanatoriums and 5,306 in the tuberculosis departments Reports from the state departments of health and estimates based on provisional reports of the United States Census Bureau indicate that there were in 1933 approximately 74,564 deaths from all forms of tuberculosis and 67,371 from respiratory forms From these figures it appears that only 21.7 per cent of the tuberculosis deaths occur in sanatoriums and hospitals operated for the treatment of tuberculosis Since one of the main functions of tuberculosis institutions is to remove dangerous foci of infection from the community, it seems important that more of

and twenty-one preventorium representing 1,217 beds averaged 1,051 patients per day

According to the foregoing figures there were 20,558,625 treatment days in the tuberculosis sanatoriums, 4,251,520 in the tuberculosis departments and 383,615 in the preventorium—a total of 25,193,760 treatment days in the 592 institutions that reported Five hundred and sixty-three other institutions, mainly tuberculosis departments, reported a day's census of 12,910 patients Accordingly, the tuberculosis institutions in the United States have an average daily census of approximately 81,952 patients and a total of 29,905,910 treatment days annually

The average daily census of patients is shown by states in table 8 and according to institutional control in table 10. The latter table shows a daily average of 6,333 patients in the federal group, 51,178 in the other public institutions, and 11,513 in the sanatoriums, tuberculosis departments and preventoriums under private management.

5 Census of Patients on Day of Reporting—The number of patients under treatment on the day of reporting will, of course, correspond closely to the figures reported in the preceding paragraph. Reports

were awaiting admission to the other public institutions, and the private sanatoriums, tuberculosis departments and preventoriums had a waiting list of 594. At the same time there were 13,571 vacancies reported, 2,580 in federal hospitals, 5,436 in the remaining public institutions, and 5,555 in institutions under private control. Apparently, therefore, the waiting list was due to an unequal distribution in patient load.

Table 9, which represents a day's census of patients, shows 56,579 patients receiving treatment in the sana-

* Based on reports of State Departments of Health and provisional reports of the United States Census Bureau.

were received from 459 sanatoriums, 680 tuberculosis departments and sixteen preventoriums, representing 92,339 beds, or 97 per cent of the total capacity. These institutions indicated that at the time of their report 81,652 patients were receiving hospital treatment for tuberculosis, 27,229 men, 20,487 women, 8,079 children and 25,857 not classified. The sanatoriums were treating 56,579 patients, the tuberculosis departments 24,288, and the preventoriums 785.

The waiting list totaled 9,854 patients. There were 317 on the waiting lists of federal hospitals, 8,943

toriums, 24,288 in the tuberculosis departments, and 785 in the preventoriums. Table 10, which summarizes the main facts about patient population on the basis of institutional control, lists 8,375 patients present in federal institutions, 61,166 in other public institutions, and 12,111 in the private sanatoriums, tuberculosis departments and preventoriums.

6 Average Length of Stay—Five hundred and thirty-two tuberculosis institutions representing 74,881 beds furnished information regarding the average length of stay of the patients treated. There were 422

sanatoriums with a capacity of 61,234 beds which reported 118,008 patients treated and a total of 19,643,640 treatment days. This indicates an average length of stay of 166 days per patient, a figure similar to that reported by Drolet but somewhat lower than the average reported by the National Tuberculosis Association following its survey of 1931.

According to the accompanying tabulation the federal sanatoriums have an average length of stay of 172 days the state sanatoriums 166, those operated by counties average 173, municipal sanatoriums 170 days, the sanatoriums operated jointly under city and county manage-

treatment days, the average length of stay is 170 days. This group of institutions shows the following averages by states:

In 110 tuberculosis departments representing 13,647 beds there were 40,327 patients treated and 4,073,027 hospital days. This indicates that the average length of stay for the whole group is 101 days. These institutions represent mainly the larger departments, however, which resemble the regular sanatoriums in organization and function. Eighty-one tuberculosis departments in general hospitals showed an average length of stay of ninety-two days. No information is

Average Length of Stay

| Control | No of Sanatoriums Reporting | No of Beds Represented | No of Patients Treated | No of Treatment Days | Average Length of Stay |

ment average 165, and, as might be expected, the sanatoriums under private control show the lowest average length of stay, 151 days.

In 261 state and local public sanatoriums, representing 46,780 beds, 93,139 patients treated and 15,805,595

available regarding the length of stay in the other 337 departments of general hospitals except what inference can be made from the fact that they admitted 14,197 patients during a twelve months period and had 3,095 patients remaining on the day of reporting

7 *Condition of Patients on Admission*—Four hundred and ninety-four institutions, representing 73,335 beds, reported on the condition of patients on admission. All together, 89,237 patients are included in this study, as shown in table 11. The reports indicate that 76,797, or 86.1 per cent of the patients, were tuberculous, 8,140, or 9.1 per cent, were diagnosed as

in 1926 Drolet reported 16, 34 and 50 per cent. The gradual increase in the admission rate of far advanced cases and the corresponding decrease in the minimal classification may not be alarming in any way but merely indicative of increased facilities for the isolation and treatment of far advanced, infectious cases of pulmonary tuberculosis

8 *Condition of Patients on Discharge*—Reports on the condition of patients on discharge were received from 507 institutions representing 74,650 beds. The results obtained are listed by states in table 12 and are classified according to adult and childhood type

nontuberculous, and 4,300, or 4.8 per cent, were unclassified

Of the tuberculous patients, 87 per cent were pulmonary cases 87 per cent childhood type, and 4.3 per cent nonpulmonary forms. These figures correspond closely to the rates of 88, 8 and 4 per cent obtained by the National Tuberculosis Association in its survey of 1931

In the group of frank pulmonary tuberculosis, 66,861 patients in all, it was found that 13.1 per cent were admitted in the minimal stage, 29.7 per cent as moderately advanced, and 57.2 per cent as far advanced. The findings of the National Tuberculosis Association in 1931 were 16.30 and 54 per cent respectively, and

Of the 67,021 patients listed under the adult type classification, 7.5 per cent were discharged as "arrested," 9.8 per cent "apparently arrested," 11.6 per cent quiescent," 30 per cent "improved," 17.2 per cent "unimproved," and 23.9 per cent died. A favorable result was obtained, therefore, in 58.9 per cent of the cases. These figures are practically identical with the report of the National Tuberculosis Association in 1931, when 17 per cent were listed as "apparently arrested" (includes "arrested" cases), 4.1 per cent "quiescent and improved," 19 per cent "unimproved or progressive," and 23 per cent died

The childhood group with reports on 8,164 patients showed, of course, a much higher rate of successful

treatment, 93.3 per cent. There were 27.9 per cent "apparently healed," 12.5 per cent "inactive," 52.9 per cent "improved," 4.4 per cent "unimproved," and 2.3 per cent died.

culosis departments, and 1,667 in the preventoriums. The federal sanatoriums have 328 children's beds, the state sanatoriums have 3,170, those under county control have 3,165, the municipal sanatoriums have

The results obtained in the treatment of extra-pulmonary tuberculosis are included in the foregoing classifications. No figures were available for a separate listing.

HOSPITALIZATION OF CHILDREN

There are in the tuberculosis institutions 11,647 beds for children, 9,036 in the sanatoriums, 944 in the tuber-

culosis departments, and 1,667 in the preventoriums. The federal sanatoriums have 328 children's beds, the state sanatoriums have 3,170, those under county control have 3,165, the municipal sanatoriums have 1,001, those operated jointly under city and county management have 480 beds, and the privately owned sanatoriums have 892. All together, 230 sanatoriums, thirty of the principal tuberculosis departments, and twenty-nine preventoriums admit children. The replies to the questionnaire indicate that in addition to the preventoriums there are 161 sanatoriums and fifteen

tuberculosis departments which accept childhood tuberculosis, contacts and other nontuberculous children. One hundred and twenty of the sanatoriums that admit childhood tuberculosis also receive children with pulmonary tuberculosis of the adult type.

Many of the sanatoriums admitting children have a waiting list for adults. This creates a problem worthy of special consideration by those in charge of tuberculosis institutions, for in the crusade against tuberculosis it seems more important to remove dangerous foci of infection from the community than to seek prevention through the hospitalization of nontuberculous

units there may be need for individual segregation, for sixteen of the twenty-nine preventoriums reported 2,479 patients admitted, of whom twelve were adult type tuberculosis, 424 childhood type, twenty-four had extrapulmonary lesions, 1,326 were nontuberculous, and 693 unclassified.

Four tuberculosis departments and 120 sanatoriums have separate buildings for children. In others, the children are segregated in wards or separate rooms but may be in close proximity to the adult patients. Although by far the majority of sanatoriums provide adequate segregation, there are some in which the

children. It is generally conceded that the important feature, from an epidemiologic point of view, is the isolation of tuberculous patients who give off tubercle bacilli. Hence, many institutions aim to make adequate provisions for the care of adults and children with open parenchymal lesions before they attempt the hospitalization of other children as a secondary preventive measure.

Every one will agree that adequate isolation facilities are essential in institutions which admit both tuberculous and nontuberculous patients. Even in the independently operated preventoriums which are separate

adults and children come in contact during meals, in their walks to and from wards, on the sanatorium grounds, at entertainments, and through the simultaneous use of solariums. In a few sanatoriums it was observed that children with pulmonary tuberculosis were hospitalized together with other children in the preventorium unit. The need for isolation facilities in the tuberculosis sanatoriums is apparent when one considers that, of the 12,629 children admitted, 1,191 had adult type tuberculosis, 6,659 the childhood type, 824 had extrapulmonary lesions, 3,236 were nontuberculous, and 701 were unclassified.

The use of sanatorium facilities for nontuberculous children is, of course, a secondary development, for the sanatoriums were originally established for the isolation and treatment of tuberculous patients. No one will deny the value of hospital care for undernourished and
